

MESSRS. A. FULLARTON & CO.

Beg to inform those interested in Farming, and especially the numerous Subscribers to their 'Rural Cyclopedia,' that they have purchased the entire Stock and Copyright of

"THE FARMER'S CASH BOOK AND LEDGER, AND SUPPLEMENTARY FARM ACCOUNT BOOKS EXPLAINED AND ILLUSTRATED,"

a work recently compiled (and issued to a few Subscribers only, resident in this neighbourhood), by

"EDWARD POND, Esq., Farmer's Accountant, Edinburgh,"

TO WHICH THEY HAVE AFFIXED

A Treatise on Farm Account Keeping with reference to Mr. Pond's System,

by a party versant in Book-keeping, by the adoption of the suggestions in which, it is believed, the working of Mr. Pond's system will be greatly facilitated, and some apparent practical difficulties obviated or removed.

Messrs. A. Fullarton & Co. have long been persuaded of the desirableness of having a simple, uniform and practical system of Book-keeping, adapted to the habits, leisure, and operations of British Farmers, and sincerely think that the foregoing Treatise and exemplifications will possess these valuable requisites.

Besides a system of Book-keeping, this Treatise contains a valuable

"TABLE OF COMPARATIVE FEEDING OF FATTENING CATTLE,"

prepared with great care and labour, and of the utility of which the highest authorities have pronounced most favourably. Without the Treatise the Farmer's Cash-Book and Ledger sold at 7s. 6d. each, but Messrs. Fullarton & Co., grateful for their support, propose to give it to Subscribers to their works at 5s. each. Their Deliverer will exhibit a copy, and receive Orders, which will be punctually attended to.

NOTICES OF THE PRESS.

"We do not know whether Mr. Pond or any practical agriculturist or accountant could have published a work more needed by farmers than this. There is, perhaps, no department of industry which demands more constant and correct attention to book-keeping than farming. Its branches are so many and diversified, the deliveries from one branch to another so complex, and the whole machinery so intricate, that only the most careful and continuous accounts could preserve from confusion. On a farm, the byre gives to the crop, and the crop to the byre; the dairy to the house; the stock to the dairy; and so on backwards and forwards, so that much additional difficulty is created. For all that, farmers have never been famed for keeping books, and we are much mistaken, if no small amount of sterling cash has not in consequence slipped through their fingers. We do not exaggerate when we say, that some farmers are not very sure at the end of the year whether they have lost or gained by their outlay and labour during the past season, and have no means of proving or estimating the amount either of their profit or loss. Others guess at it by the balance in their bank-book or the cash in hand, coupled with a vague conjecture of the sums due to or due by them. Taking the very favourable case, where accurate cash books are regularly kept and balanced, we believe that in nine hundred and ninety-nine cases out of a thousand, they merely show when balanced the gross profit or loss. Suppose there is a loss shown, there is no way of discovering on what department of the farm loss is sustained, or by what it is caused; whether it is on the stock, or on crops, or on the dairy; nor is there any proper method of checking the waste or pilferings of servants. This is, of course, pure groping in the dark, and, like all such gropings, leads to not a few hard knocks and falls every now and then. We cannot, in the brief space we can afford, give any intelligible description of Mr. Pond's system; but we may safely hazard the assertion, that it will, if regularly followed, present at a glance a view of the profit and loss on every distinct department of the farm, as well as in the aggregate, and thus enable the agriculturist, if his possessions are paying or not paying, to tell on what branch the gain or deficit occurs, and to act accordingly."—*Weekly Register*, 30*th Aug.* 1848.

"The author seems to have bestowed very great attention and care in the preparation of the work, and the remarks which he introduces under each department of farm economy, while they show his knowledge of a system of good management, at the same time tend to make the work interesting and instructive beyond its real purpose. We have no hesitation in recommending this work as one calculated to be of great benefit to those to whom it is particularly addressed; in our opinion, this work supplies a great desideratum in agriculture."—*Caledonian Mercury*, 24*th Aug.* 1848.

"The author appears to have a full knowledge of the practical details of farming, and is conversant with systematic management, the benefit of which he has conveyed to others in a sensible and concise form. We can recommend the work as one of great practical utility, and as forming an important element in an agricultural education."—*Edinburgh Evening Courant*, 24*th Aug.* 1848.

"Mr. Pond, the author of this work, has certainly directed his attention to a subject which has been almost altogether overlooked in the curriculum of an agricultural education, viz., a system of Farm Book-keeping. Without a farmer has a system of book-keeping, and carefully followed out, there is not much chance of his successfully adapting his knowledge of chemistry to agriculture. We cannot but look upon this work as a means of instructing in accuracy of detail, without which, book-keeping, far less chemistry, will be of little avail.—*North British Railway and Shipping Journal*, 26*th Aug.* 1848.

QUAIL,—scientifically *Coturnix*. A genus of gallinaceous birds, of the grouse or partridge family. They are very nearly allied to partridges, but have a smaller body, a slenderer bill, and a shorter tail, and have neither spurs nor red eyebrow. The common quail, called by the old naturalists *Tetrao coturnix*, occurs from Iceland to Southern Africa, and from Britain to China, and is celebrated for its migrations, and is everywhere esteemed as excellent food, and is probably the bird which the patient and all-benign Governor of the Universe gave to the murmuring Israelites as food in the wilderness. It migrates northward in spring and southward in autumn; it alights in clouds on many parts of Continental Europe; it swarms so greatly at the time of migration in Southern Russia and in some countries around the Mediterranean as to be caught by thousands; and though naturally scarce and comparatively poor in Britain, it is imported alive, in great numbers, from France and Germany, to supply the market of London. The male bird is 7½ inches long and 14 broad; his bill is dusky; his head, neck, and back are a mixture of brown ash-coloured and black; the crown of his head and the space above each eye are streaked with a whitish yellow line; his chin, throat, belly, and thighs are dirty yellowish white; his scapular feathers and those of his back are streaked in their middle with light yellow, and on their sides with rusty-brown and black; his wing-coverts are reddish brown, and elegantly barred with black-bounded paler lines; his quills are lightish brown, with small rusty bands on the exterior edges; his breast is of a pale rust colour, spotted with black, and streaked with pale yellow; his tail consists of twelve short feathers, barred with black and very pale brownish red; and his legs are pale brown. The female has less vivid colours than the male, and has no black spots on the breast or side feathers. The nest is a mere hollow on the bare ground, or at best a scooped seat of a few dry leaves or stalks; and it generally occurs among field crops of grass or clover or especially wheat. The eggs vary, in different countries, from 6 to 20; and have a whitish colour, marked with irregular rusty spots. The incubation extends through about three weeks. The young birds, like those of the partridge, run as soon as they leave the shell, and occasionally abandon the mother and begin to be entirely independent of her so early as the eighth day. The quail feeds on seeds, grain, green leaves, and insects; and grows much fatter than the partridge; and is exceedingly indolent; and neither rises soon before the dog nor flies far upon the wing. It is easily inveigled into a net by means of a call in imitation of its natural cry; and it is sought after by the fowler from the period of its arrival in spring till the month of August.

QUARRYING. Large blocks of stone are only to be procured in rocky places, and the openings or excavations made for obtaining them are called *quarries*. When once a quarry has been opened and is found capable of yielding a large quantity of stone, the qualities of which have been tested by long use and experience, it becomes a very valuable property. From the weight of the material produced, a quarry is unworthy of prosecution unless it has the advantage of water conveyance, and of a railroad for transporting the material to the water's edge; and even with every advantage, it requires considerable forethought and skill to work it with continued advantage. A quarry is seldom a deep excavation like a mine, but consists of working a way into the side of a hill. One of the first things to attend to, therefore, is not to begin the work too low, so as to get the quarry into a hole, from whence it may be very troublesome, dan-

gerous, and expensive to raise large masses of stone, but a road leading into it should be formed and maintained with as gentle a slope as possible, in order that horses may draw the stones up as produced. It is better in the first instance, to so arrange as to deliver the first stones obtained, down hill, instead of having to raise them. But it must be kept in mind, that the elevated stone, and particularly such as outcrops and is visible; and has been exposed to the air, perhaps for centuries, is never so good and sound as that which is hidden or has been protected; and pressure also seems to improve the formation of stone, for that which is deeply situated in the quarry is generally more hard, compact, durable, and better in every respect than that found near the surface, which is tender and friable. On this account it may be necessary to work downwards, but this should be done gradually and with caution.

The first operation should be to remove the incumbent soil (which is called *uncallowing*) to such an extent as will expose the extent of the masses of stone fairly to view. They are called masses, because although the whole rock may seem to be but one mass of stone, yet on closer inspection it will be found, in almost every case, subdivided by natural joints and fissures, too small, perhaps, even for the introduction of a common nail, but in which the stone has little or no natural adhesion; and consequently, at such places one block will readily part from another, without fear of breaking either of them, if the operation is conducted with due skill and care. The horizontal, or nearly horizontal joints or fissures, will be seen without difficulty from the front, and it seldom happens that they are more than from one to four feet asunder, or one below the other. Vertical fissures do not always exist, but if they do, they will be just as obvious as the others. Having found these, the top of the stone must be searched (first moving all that is above it) for the fissure, in a nearly vertical position that corresponds with the front, and should this be found, the entire block of stone that can be obtained in one piece will be seen. The two end blocks that are contiguous to it must now be examined in the same way, in order to determine which of the three blocks shall be sacrificed: for the greatest difficulty is to get out the first block, on account of its being tightly wedged or jammed in by the end ones. One or other must, therefore, be broken, either by a short and heavy miner's pick-axe, or by blasting with gunpowder, or by gads and the hammer; the gad being a thick wedge of hard steel that is held in its proper position, about four or six inches from the fissure, by the two hands of one workman, while it is powerfully struck upon with a sledge-hammer by another, until a sufficient quantity of stone is cut away, to permit the stone that is required to be shifted or moved in a sufficient degree by small wedges driven behind it, under it, and on the undisturbed side of it, to cause it to become detached from its natural bed, when it will be ready for removal: and this, it might be supposed, would be effected by the application of strong iron crowbars or levers to it in the first instance, so as to raise it sufficiently to get hard wooden rollers under it, by which it might be transferred to a platform, inclined plane, or truck, prepared to receive it, and such accordingly is the method adopted for the removal of all large stones that come up with broken or irregular sides and edges, and which will, therefore, require to be *scabbled* or rough dressed by a stonemason, before they can be delivered or used. But, as the value of all large and fine stone is much enhanced by its magnitude, by having no cracks or flaws in it, and by having its faces as flat as possible, and its angles sharp or unbroken, so that the mason in working it need not cut much to waste, the introduction of wedges or levers of sufficient strength to raise its weight, could not fail to destroy its figure by breaking away the edges, and it is, therefore, found more advantageous to lift it from above, than to raise it from below, or at any rate, to have both forces in operation at the same time, so as to cause the lifting action to diminish the weight. This is effected by a very ingenious device well known to every mason under the name of a *Lewis*.

When the natural vertical fissures before spoken of do not occur in blocks of stone, or whenever it may be desirable to raise smaller blocks than they would produce, fissures or cracks must be produced artificially; and this is usually done by drilling a line of holes into the stone at regular short intervals, in the straight lined direction in which the separation is required; a row of conical steel points, rather larger than the holes, are then set one into each hole, and a number of men strike with hammers simultaneously upon them, which, if done equably, never fails to produce a separation of the piece of stone in the direction required. If the stone is found to cleave easily, dry wooden pegs, previously cut larger than the holes, and driven in the same way, will answer the purpose, and is most frequently resorted to for obtaining blocks both of granite and marble in this country. Should the wooden pegs fail, a bank or wall of clay must be built around them capable of holding water, and on filling this, so that the water can sink into the pegs, they will swell with such force as never fails to separate the mass, provided hard and perfectly dry wood has been used.

The drilling of hard stone cannot be effected by ordinary revolving drills. The drill made use of is a steel cold chisel, eighteen inches or two feet long, its breadth being equal to the diameter of the hole to be produced, and its edge being double bevelled and not too acute or sharp. It is held by a workman over the place where the hole is to be made, and struck with a hammer in the other hand, or by a separate man, when the stone is very hard and the hole large. Between each blow of the hammer, the chisel (called a drill) is turned partly round, and is kept revolving or moving backwards and forwards, so that two cuts or blows never come in the same direction, but make a series of indentations like a star, and the powdered stone falling to the bottom, is taken out by a kind of screw-formed spoon, like a screw auger. In this manner holes are made more speedily than might be expected, and they are usually paid for by the inch, according to their size and depth.

The process of blasting rocks by gunpowder requires the same holes to be drilled, but for this purpose they must be deeper and larger than for splitting rocks. From half an inch to three-quarters diameter, and six or eight inches deep will, generally, be sufficient for the splitting holes, while eighteen inches to two feet is a common depth for those used in blasting, and they should not be less than half an inch in diameter. The gunpowder, for convenience of introducing it, is sewed in a linen or flannel bag, or cartridge, having a train that is confined in a straw or small reed; or, if the hole is wet, the cartridge is made of tin, with a fine tin tube to contain the train. Having introduced the powder, dry sand is put upon it, and rammed down, when the remainder of the hole is filled with sand a little moistened. This is called, tamping a hole. Some wild-fire, or powder kneaded with water, or slow match, made of paper, or old linen soaked in saturated solution of nitre, is

made to communicate with the train, and this must be so arranged as to give the person firing it time to retreat before the powder explodes, as fragments of the stone are frequently dispersed with such violence as to be very dangerous. The most hazardous thing in *shooting a hole*, as miners call this operation, is when, by improper fixing of the match, the whole charge explodes the instant the fire touches it, or where it hangs fire, or is so long before it explodes that the workman imagines the match has been extinguished; and, perhaps, goes to inspect it at the very time when it explodes. From both these causes very serious accidents have occurred, and no one ought to approach a hole after the match has been lighted, until such a period has transpired as must render an explosion impossible.

As marble and granite have always to be transported, unless used upon the spot where they are produced, it may be useful to remark, that fourteen cubic feet are considered as equal to a ton weight, on which account a considerable loss frequently accrues to the purchaser; for the cubic quantities are taken by weight, to determine the freight, instead of by measurement; and as the above proportion is not a true one, the cubic feet rarely measure to what is marked upon the stone, or what they are sold for, particularly when it is hard, good, and compact. But lighter and more porous stone will, on the contrary, yield more than fourteen feet to the ton.

QUARTER. The fourth part of any thing; or a division of a carcase comprising one of the limbs; or twenty-eight pounds weight; or a measure of grain equal to eight bushels.

QUARTER-ILL. See Inflammatory Fever.

QUARTZ. A well known mineral species, which surpasses all others in the extent of its distribution. It is also one of the most comprehensive in the varieties it embraces, which are especially numerous as respects colour, lustre, and fracture. Its contents have very improperly been swollen, however, by the introduction of many substances which consist of mixtures of quartz with other species; and the difficulty of forming a correct idea of this group of minerals has been enhanced by their being separated into several species and sub-species, as has been done in certain treatises on mineralogy. We shall endeavour, in the first place, to take a scientific view of quartz; after which we shall point out those varieties which have, from various causes, obtained distinct appellations, together with the mixtures of quartz with other minerals, usually considered as varieties of the species; and, finally, the varieties which are employed in the arts.

The crystals of quartz are, for the most part, regular six-sided prisms, terminated at one or both of their extremities by six-sided pyramids, the faces of which correspond to the sides of the prism, and meet under an angle of 141° 40′. It sometimes happens that the prism intervening between the two pyramids is very short, or even extinct; in which case the form becomes the dodecahedron, with isosceles triangular faces. In the six-sided prism with pyramidal terminations, we often observe the solid angles, situated between the prism and the pyramid, replaced by rhomboidal planes. The alternate faces of the prism are striated horizontally. The primary form is a rhomboid of 94° 15′ and 85° 45′, parallel to whose planes cleavages may be obtained, as also to the planes of the dodecahedron, with isosceles triangular faces, which might also be regarded as the primary form of the species; but the former figure is preferred on account of its simplicity. Lustre vitreous, inclining, in some varieties, to resinous; colour white prevalent; among the brightest colours are violet-blue, rose-red, clove-brown and apple-green. Dark brown and green colours are generally owing to foreign admixtures Streak white; transparent, translucent, frequently opaque, but never, perhaps, unless occasioned by other minerals; hardness between felspar and spinelle; specific gravity 2·69. The crystals often present macles, and sometimes we observe larger crystals, apparently made up of innumerable smaller ones, all of which are so aggregated that their similar faces coincide as respects direction. Implanted globules, reniform and stalactitic shapes, are other modes of occurrence with compound varieties of this species. These have smooth, granulated and drusy surfaces; composition (mechanical) columnar, often impalpable, and frequently a second time composed into granular or curved lamellar masses. The massive varieties present a granular or columnar, and often an impalpable composition, in which case the fracture becomes conchoidal and splintery. Sometimes a second composition produces indistinct granular or thick lamellar masses. Certain very thin columnar compositions, if cut *en cabuchon*, parallel to the fibres, show an opalescent light. We have pseudomorphous crystals, also, of this species, in the shape of cubes, octahedrons, and various other forms, derived from fluor, calcareous spar, gypsum, &c. besides which, quartz occurs in globular and tuberose masses, formed in vesicular cavities, and also in plates and pebbles. The principal varieties of quartz, which are known by distinct names, are the following: 1. *rock crystal;* 2. *smoky quartz;* 3. *yellow quartz;* 4 *amethyst;* 5. *siderite,* or *blue quartz;* 6. *rose quartz;* 7. *milky quartz;* 8. *irised quartz;* 9. *common quartz;* 10. *fat* (*greasy*) *quartz;* 11. *flint;* 12. *hornstone;* 13. *Lydian stone;* 14. *floatstone* (*swimming stone*); 15. *fibrous quartz;* 16. *radiating quartz;* 17. *chalcedony;* 18. *carnelian;* 19. *chrysoprase;* 20. *agate.* Rock crystal is applied to the transparent and colourless crystals, and more particularly to those of a large size. Smoky quartz consists of those crystals and crystalline masses which are translucent and of a brown colour. Yellow quartz, sometimes called, also, *Bohemian* or *Scottish topaz,* is transparent, and of various shades of yellow. Amethyst, also in crystals, and for the most part nearly transparent, is of every shade of violet. Siderite, or blue quartz, is never in regular crystals, but usually compact, and of an azure-blue colour. Rose quartz is confined to translucent massive varieties, of a delicate rose-red colour. Milky quartz is also massive, having an uneven fracture, is translucent, and of a milk-white colour. Irised quartz embraces such crystallized varieties as exhibit in patches, at or beneath the surface, the colours of the rainbow. Common quartz differs from milky quartz simply in being destitute of the milky whiteness of that variety, or in having an inferior degree of whiteness, and more of a vitreous lustre. Fat or greasy quartz differs from common quartz merely in lustre, which, instead of being vitreous, has the appearance of having been immersed in oil. Flint has a more compact texture than common quartz, is dull, only translucent on the edges, of a brownish colour, and breaks with a conchoidal fracture. Hornstone closely resembles flint, from which it can scarcely be distinguished, except in its conchoidal fracture, which is much less distinct. When replacing the fibres of

wood, it is called *woodstone*. Lydian stone, sometimes called *flinty slate*, differs from flint chiefly in having a darker colour, less translucency, and a fracture somewhat slaty; when black, it is often called *bassanite*. Floatstone consists of a delicate tissue of minute crystals, visible only under a powerful magnifier. Owing to the cavities it contains, it sometimes will float on water. Fibrous quartz consists of those varieties which are in distinct, parallel concretions. Radiating quartz is like fibrous quartz, except that the fibres diverge from a common centre, and resemble the radii of a circle, instead of being parallel. Chalcedony includes those varieties of radiating quartz, where the thickness of the individuals becomes so much diminished as to render them nearly or altogether impalpable; its masses generally offer a mammillary or stalactitical surface, and the lustre on freshly-broken surfaces is feeble. Carnelian differs from chalcedony merely in having a blood-red colour. Chrysoprase also resembles chalcedony in composition, excepting that the individuals of which it is made up, appear to be grains instead of fibres; its colour is apple-green, from the oxide of nickel. Agate implies the occurrence of two or more of the above varieties, existing together in intimate union; or it may be applied to a single variety, provided it offers different colours in the same specimens.

Those substances which have formerly been included under quartz, and which are mixtures only of this mineral with other species, are the following: 1. *cat's eye;* 2. *avanturine;* 3. *prase;* 4. *plasma;* 5. *heliotrope;* 6. *iron flint;* 7. *Compostella hyacinth;* 8. *jasper* (*red, brown, striped* and *porcelain*); 9. *jasper-agate;* 10. *Mocha stone;* 11. *Venus-hair agate.* Cat's eye consists of transparent quartz traversed by exceedingly delicate parallel fibres of asbestus; when cut *en cabuchon,* it exhibits, as its position is altered to the eye, a peculiar play of light upon its surface, resembling the changeability of light seen in the eye of a cat. Avanturine is quartz penetrated by small golden-coloured spangles of mica. Prase is quartz penetrated by green fibres of hornblende, which are often so small as to escape detection by the naked eye, and their presence is only discoverable from the green colour they impart. Plasma is a variety of chalcedony, coloured leek-green by some substance not yet examined. Heliotrope is likewise a variety of chalcedony, but coloured by green earth, and occasionally dotted with minute portions of red jasper. Iron flint consists of quartz, intermingled throughout with oxide of iron. The Compostella hyacinth is a red variety of iron flint, in regular six-sided prisms, with pyramidal extremities, which occurs imbedded in gypsum. Jasper differs from the two last varieties in being massive, and in containing variable proportions of clay. Red and brown jasper simply allude to the colour of the compound. Striped jasper appears to contain a larger portion of clay, and is distinguished on account of its striped delineations. Porcelain jasper is regarded as siliceous slate altered by heat, and is found in the vicinity of coal-mines. Those varieties which are found in rounded masses, and which, from the concentric layers of which they consist, appear to have been formed in open spaces, are called *Egyptian jasper*. Jasper agate consists of those varieties of jasper in which several colours are so arranged as to produce an agreeable effect. Mocha stone consists of agate, containing appearances of vegetable filaments, which have been occasioned through the infiltration of iron and manganese through its crevices. Venus-hair agate consists of quartz traversed by delicate hair-shaped crystals of any kind. The most transparent varieties of quartz are pure silex, which, according to Berzelius, contains 49·70 silicon and 50·30 oxygen. Hornstone, flint and chalcedony agree with it in composition. Several varieties contain small quantities of alumine, lime, oxide of iron, &c. Chrysoprase contains 0.01 oxide of nickel.

Quartz is infusible before the blow-pipe, and shows itself to be pure silex. It is dissolved by soda easily, and with effervescence. Two pieces rubbed together emit an empyreumatic odour, and a phosphorescent light. Crystals of quartz may be obtained from a solution of silica in fluoric acid, or in potash diluted with water. The fluid from which crystals of this species are formed, in geodes and other natural cavities of rocks, has been observed to be chiefly water.

With respect to the distribution of quartz, and which we have remarked above to be the most abundant mineral known, it may be said that common quartz enters into the regular mixture of various rocks, of granite, gneiss, mica slate, topaz rock, &c. In others, it occurs in single crystals and in grains, as, for instance, in porphyry, and is frequently met with in the vesicular cavities of amygdaloidal rocks. In these last situations, in particular, are found the finest varieties of chalcedony, carnelian, of jasper and agate. Hornstone forms globules and irregular veins in compact limestone; and flint occurs in a similar manner, but disposed through vast beds of chalk. Quartz, also, occurs in rocks, of which it does not form a regular ingredient; sometimes in masses that are open in their interior, and lined with crystals of enormous size. It also exists in beds by itself, as in quartz-rock, and some varieties of sandstone. Striped jasper and flinty slate form, also, particular beds. The varieties prase and chalcedony, as well as amethyst, are often found in beds of iron ore. River sand, and that of extensive plains, where it is sometimes so fine as to drift before the wind, are formed chiefly of quartz. Common quartz, and several other varieties, are spread all over the earth, but certain varieties are confined to a few localities. The finest and largest rock crystals are found in the Alps of Salzburg, the Tyrol, Switzerland, Dauphiny, Piedmont, and Savoy; also in the isle of Madagascar, Ceylon, and Brazil.

Several varieties of quartz are of important use in the arts and manufactures, and have long been employed for purposes of decoration and utility by mankind. The most important applications of this species to useful purposes, depend upon its being composed of silex. Quartz enters into the composition of glass, both white and coloured. It is added to the mass of porcelain, in the state of an impalpable powder, and forms part of the paste, also, in other kinds of pottery. It is used as a flux in the melting of several kinds of ores, particularly those of copper, and in other metallurgical processes. The use of flint in gun-locks is well known. Lydian stone is employed for trying the composition of mixtures of gold and silver. Sandstone yields various applications for architectural and other purposes, as the construction of melting-furnaces, mill-stones, &c. A variety of sandstone from Villa Rica, in Brazil, which is flexible, deserves to be spoken of in this place. Its flexibility is probably owing to scales of mica disseminated through its mass. Sand, with slaked lime, forms mortar. It is also used, in some countries, for the improvement of roads. See the articles SILICA and SAND.

QUASSIA. A small genus of ligneous, evergreen, tropical plants, of the simaruba order. The bitter species, *Q. amara*, was introduced to Britain from Guiana in the latter part of last

century, but is still rare in collections. It is a very ornamental plant, of naturally about 20 feet in height, and carries red flowers in June and July; and, in common with most or all of the other plants of the simaruba order, it is distinguished for a powerful medicinal bitterness, of great service in dyspepsy, nervous irritability, intermittent fever, dysentery, and kindred diseases. But the two species which furnish the quassia wood and quassia bark of our pharmacopœias, though formerly ranked as true quassias, are assigned by modern botanists to the genus simaruba. See the article SIMARUBA. The peculiar principle of quassia wood, or the dry, brittle, semitransparent, brownish-yellow substance which is left by the evaporation of an alcoholic or watery infusion of it, has been called quassine.

QUEEN-BEE. See BEE.

QUEEN OF THE MEADOW. See MEADOW-SWEET.

QUERCITRON, — botanically *Quercus Tinctoria.* A hardy, deciduous, economical tree, of the oak genus. It is a native of North America, and was introduced to Britain in 1739. It ranks among the red American oaks, and has naturally a height of about 70 feet. Its leaves are sinuate, and have mucronate lobes; and its inflorescence appears in May. Its timber possesses considerable economical value, but is inferior to that of the common oak. Its bark is a well-known and important dye-stuff; and is much employed in dyeing wool, silk, and paper hangings; and is said by Dr. Bancroft, who introduced it to notice, to be equal in power to ten times its weight of woad. With a basis of alumina, a decoction of the bark gives a bright yellow dye; with oxide of tin, it gives a variety of tints, from pale lemon to deep orange; and with oxide of iron, it gives a drab colour. The cellular integument of the bark is what contains the colouring matter.

QUERCUS. See OAK, KERMES OAK, CORK-TREE, ILEX, and QUERCITRON.

QUERN. A hand-mill, comprising two stones, for the grinding of corn in small quantities. It is very ancient, and of very simple structure; yet it is still used in Shetland and some other remote districts of Britain.

QUEY. A young female of the ox species,—intermediate in age between a she-calf and a heifer.

QUICKBEAM. See ASH (MOUNTAIN).

QUICKEN-TREE. See ASH (MOUNTAIN).

QUICK-LIME. See LIME.

QUICKSAND. See FOUNDATIONS.

QUICKS. See AGROSTIS and QUICKSET HEDGE.

QUICKSET HEDGE. A fence of living plants, as distinguished from a dead hedge,—and especially a fence of hawthorn as distinguished from all less resistive fences. The latter also bears the name of quicks. See the articles FENCE, HEDGE, and HAWTHORN.

QUICKSILVER. See MERCURY.

QUIDDING. A temporary cause of unsoundness in a horse,—tending to render him incapable of active work. It consists in the rejection of his hay in a rolled-up form like a quid of tobacco; and arises immediately from inability to masticate the hay, and remotely from a defect in the grinders, or from considerable tenderness of the mouth and pharynx.

QUILLS. The hard and strong feathers of geese, swans, turkeys, crows, ostriches, and some other birds. They are denominated according to their natural numerical order in the wing; and those called seconds and thirds have the largest and roundest barrels, and are the best for writing. Prepared or clarified quills are comparatively good or bad according to the size and solidity of their barrels, according to their weight, and according to their relative degrees or mutual combination of hardness and elasticity. Large quantities are annually imported into Britain from Holland, Germany, and Russia. Their barrel consists of coagulated albumen. See the article FEATHERS. The quills of crows are used principally for drawing.

QUILLWORT,—botanically *Isoetes.* A small genus of curious aquatic plants, of the marsileaceous division of cryptogams. The marsh species, or European quillwort, or Merlin's grass, *Isoetes palustris,* inhabits the shallow parts of limpid upland lakes in the mountainous districts of Britain. It has a perennial tuberous root, and sends down from it long, simple, and somewhat hairy fibres perpendicularly into the ground, and has no stem, and comprises a tuft of many quadrangular awl-shaped fronds of from 3 to 9 inches in height, and carries a brown inflorescence from May till October. Fishes are said to feed and fatten on it.

QUINA. See PERUVIAN BARK.

QUINCE,—*Cydonia.* A small genus of hardy, deciduous, fruit-shrubs and fruit-trees, of the rose-tree order. Three species are in cultivation; but the common one of these, *Cydonia vulgaris,* is by far the most interesting. It has crooked branches, and a spreading, bushy head. It is indigenous to Germany and the south of Europe; and it appears first to have attracted notice in the city of Cydon, in Crete or Candia—whence its botanical name, *Cydonia.* The fruit is of a fine golden yellow, and more nearly resembles that of the orange than any other. It was even more highly esteemed by the Greeks and Romans, for preserving, than by us. "Quinces," says Columella, "not only yield pleasure, but health." The quince seldom grows higher than fifteen feet, and is usually rather a shrub than a tree. Its large white and pale pink blossoms, which appear rather later than those of other fruit trees, are quite ornamental; and the tree, properly grown, is very ornamental when laden in October and November with its ripe golden fruit. Three chief varieties of it occur in gardens,—the apple-shaped, the pear-shaped, and the Portugal; but only the last of these is well worthy of cultivation.

The quince is, in all its varieties, unfit for eating raw. It is, however, much esteemed when cooked. For preserving, it is everywhere valued, and an excellent marmalade is also made from it. Stewed, it is very frequently used, to communicate additional flavour and piquancy to apple-tarts, pies, or other pastry. In England, wine is frequently made from the fruit, by adding sugar and water, as in other fruit wines; and it is a popular notion there, that it has a most beneficial effect upon asthmatic patients. Dried quinces are excellent.

The quince is easily propagated from seed, layers, or cuttings. From seeds the quince is somewhat liable to vary in its seedlings, sometimes proving the apple-shaped and sometimes the pear-shaped variety. Cuttings, planted in a shaded situation, early in the spring, root very easily, and this is perhaps the simplest and best way of continuing a good variety. The better sorts are also frequently budded on common seedling quince stocks, or on the common thorn. Quince stocks are extensively used in engrafting or budding the pear, when it is wished to render that tree dwarf in its habit.

The quince grows naturally in rather moist soil, by the side of rivulets and streams of water. Hence it is a common idea that it should always be planted in some damp neglected part of the garden, where it usually receives little care, and the fruit is often knotty and inferior. This practice is a very erroneous one. No tree is more benefited by manuring than the quince. In a rich, mellow, deep soil, even if quite dry, it grows with thrice its usual vigour, and bears abundant crops of large and fair fruit. It should, therefore, be planted in deep and good soil, kept in constant cultivation, and it should have a top-dressing of manure, every season, when fair and abundant crops are desired. As to pruning, or other care, it requires very little indeed — an occasional thinning out of crowding or decayed branches, being quite sufficient. Thinning the fruit, when there is an over-crop, improves the size of the remainder. Ten feet apart is a suitable distance at which to plant this tree.

QUINCUNX. A disposition of four trees at the corners of a square, and one in the middle of it. This disposition, often repeated, forms a regular grove, which, when viewed from any angle of the aggregate square or parallelogram, is seen to have equal parallel alleys. See the articles Orchard and Plantation.

QUININE. See Peruvian Bark.

QUINOA. See Goosefoot.

QUINSY. A disease in hogs similar to strangles in horses. It comprises sore throat, enlargement of the glands of the throat, and inflammation of the cellular substance between the skin and muscles beneath the lower jaw. It progresses rapidly, and causes so great a swelling as to impede breathing and threaten suffocation; yet when timeously and promptly treated, it is seldom dangerous. The proper remedies are bleeding and a good dose of Epsom salt, followed by a small dose every six hours, and the occasional offer of some weak warm washy food, till the bowels become freely opened.

QUISQUALIS. A genus of ornamental, tropical, climbing plants, of the combretum family. The Indian species, *Q. indica*, was introduced to the stoves of Britain in 1815; and is eminently beautiful. It attains a height of about 20 feet, and blooms in constant beauty and profusion from the beginning of April till the middle of October, and enlivens the whole stove with the delicious fragrance and the varying hues of its bunches of changeable orange and ruby-coloured flowers. It is easily propagated and cultivated. Two other species, the smooth and the pubescent, were introduced in the same year, and attain the same height; and all the three love a soil of loamy peat, and are propagated from cuttings.

QUITCH. See Agrostis.

QUIT-RENT, in law. A small rent that is payable by the tenants of most manors, whereby the tenant goes quit and free from all other services. Anciently this payment was called white-rent, because it was paid in silver coin, and to distinguish it from rent-corn.

QUITTOR. A fistulous sore in the coronet of the horse's foot, generally on the inside, or appearing from within at or near the junction of the skin and hoof. It is caused sometimes by direct injuries to the coronet, as by treads, abrasions, and over-reaches, — but more commonly by punctures, bruises, lacerations, pricks in shoeing, or neglected corns in the lower part of the foot,—giving rise to suppurative inflammation. The pus, finding no outlet through the insensible and unabsorbable horn, works its way upward, and discharges itself at the coronet. The ulceration has only a small opening; but, except in slight cases, it may be ascertained by the probe to extend and ramify through a considerable amount of sinuses; and if allowed to proceed without proper treatment, it effects an extensive separation of the wall of the foot from the sensible parts, and sets up inflammation in the side cartilages, and even communicates disease to the bones. In all bad cases, the services of an experienced and scientific practitioner are indispensable; and, in any cases, however slight, the blind and butcherly behaviour of those pretenders who wantonly wield the knife or the red-hot iron against masses of healthy parts as well as of destroyed ones, ought to be avoided and abhorred. "The ordinary mode of cure," says Mr. Percivall, "consists in the introduction of caustic into the sinus; and so long as the cartilage preserves its integrity, or is free from caries, this is perhaps the most prompt and effectual mode of proceeding. The farrier's practice is to mix about half a drachm of corrosive sublimate in powder with twice or thrice the quantity of flour, and make them into a paste with water

This he takes up by little at a time with the point of his probe, and works it about in the sinus until the paste appears rising in the orifice above. After this is done, he commonly has the horse walked about for an hour or two, or even sent to slow work again, which produces a still more effectual solution of the caustic, at the same time that it tends greatly to its uniform and thorough diffusion into every recess and winding of the sinus. The consequence of this sharp caustic dressing is a general slough from the sinus. Every part of its interior surface is destroyed, and the dead particles become agglutinated, and cast off along with the discharges in the form of a dark firm curdled mass, which the farrier calls the core; and so it commonly proves, for granulations follow close behind it, and fill up the sinus." But in the majority of cases which are referred to the experienced surgeon, and certainly in all bad ones, more complex treatment is requisite, and the removal of much of the sole and wall is indispensable; and in all such cases, the following practice of Mr. Newport may be followed:—"After the shoe has been removed, thin the sole until it yield to the pressure of the thumb; then cut the under parts of the wall in an oblique direction from the heel to the anterior part, immediately under the seat of complaint, and only as far as it extends; and rasp the side of the wall thin enough to give way to the pressure of the over-distended parts; and put on a bar shoe rather elevated from the frog. Ascertain with a probe the direction of the sinuses, and introduce into them a saturated solution of sulphate of zinc, by means of a small syringe. Place over this dressing the common cataplasm or turpentine ointment; and renew the application every 24 hours. I should recommend that, when the probe is introduced, in order to ascertain the progress of the cure, it be gently and carefully used, otherwise it may break down the new formed lymph." See the article FISTULA.

R

RABBIT. Several species of gnawing quadrupeds of the same genus as the hare,—or of the genus Lepus, and order Rodentia. See the article HARE.

The American rabbit, *Lepus Americanus*, *L. Brasiliensis*, or *L. nanus*, is similar in size and colour to the common or European rabbit. It has reddish feet, and has no black on either ears or tail. It nestles in the trunks of trees, and often ascends their hollows as far as to their branches. Its flesh is insipid and soft.—The Siberian rabbit, *Lepus tolai*, is intermediate in character between the common rabbit and the common hare, and occasionally exceeds the latter in size. It makes no burrows, but seeks shelter in the clefts of rocks or other cavities.—Some other species or permanent varieties, occur in other distant countries; but, like the first of the two we have noticed, and like the black-necked rabbit of India, they can be distinguished from the common rabbit, only by minute or very unimportant characters.

The common rabbit, or European rabbit, *Lepus cuniculus*, comprises almost all the varieties, both wild and tame, which occur in Europe. It is smaller than the hare, and has shorter hind legs and more thinly covered ears. Its ears also are somewhat shorter than its own head; its tail is shorter than its thigh; and its fur has predominantly a yellowish grey colour, with some red on the neck and some brown on the tail, but is whitish on the throat and belly, and grey without any black on the ears. But it varies somewhat in size, considerably in the qualities of its flesh, and very greatly in the colours of its fur, according to differences of breed and diversities in the mode of living. The wild rabbit is smaller than the tame, and is less white and less delicate in flesh, but has more of the game flavour, and brings a higher price in the market. The tame rabbit is widely diversified in both size and colour. The largest kinds are generally the best for breeding; the broad-chested and short-legged kinds are the hardiest and the most rapid fatteners; a large variety of the hare colour has more highly coloured and more highly flavoured flesh than any of the other tame kinds; large varieties of white or of white and yellow colours have comparatively very white and delicate flesh, and may be so cooked as to rival the turkey; and the varieties called French and Turkish rabbits differ little from the common kinds, yet are much esteemed.

The common rabbit, though now dispersed through most of Europe, seems to have been a native of Spain, and loves a temperate or even warm climate, and cannot without difficulty endure great cold. It abounds in many districts of Britain; and is specially plentiful in the sandy tracts of Norfolk, Suffolk, Cambridgeshire, and Lincolnshire. It is amazingly prolific, and but for being kept down by hawks, foxes, polecats, weasels, and men, it would soon

overspread entire districts and become a terribly devastating nuisance. In the time of the ancient Romans, it so swarmed in all the Balearic Islands that the inhabitants were obliged to implore a military force from the Emperor Augustus to exterminate it; and in quite recent times, it so greatly oppressed the Island of Minorca that the population had to be called out by the Governor during two days in every year to destroy it. It becomes capable of breeding at six months old, and can breed seven times in the year, and produces from 5 to 10 young ones in each brood, and lives to the age of 8 or 9 years. One calculation supposes that, in four years, a pair may multiply to the number of 478,062; and another that they may multiply even to 1,274,840. But though the latter calculation seems quite within the limits of possibility, even the former is probably never, or at least scarcely ever, within the limits of fact. A curious circumstance is, that, from the moment of birth till they reach the age of six weeks, the young are liable to be destroyed by the male; and this circumstance concurs with the predations of many keen and vigilant enemies to keep down the numbers. The female goes with young 30 or 31 days; she scratches out a burrow about two feet deep, and makes a bed of down from her own fur, in preparation for her accouchement; and she tends and suckles her young with wonderful solicitude, and never leaves them except to get supplies of food, and does her best to conceal them from the killing knowledge of the male, and leads them to the warren at the end of six weeks when they cease to be objects of his dislike.

The wild rabbit is reared in warrens, in a state of comparative liberty. It is valued partly for its fur, which is used chiefly in the manufacture of hats,—and partly for its flesh, which, though not much esteemed in Britain, is yet consumed to a considerable extent in our large towns. Warrens are exceedingly varied in both character and extent. They are most economical in sandy downs, which possess little adaptation to any other purpose; they should be enclosed by a wall, both to keep out depredators, and to prevent the rabbits from making havoc on the neighbouring fields; and, if not naturally stocked, they may be furnished at the rate of three couples to the acre, and in the proportion of one male to every 7 or 8 or 10 females. Mice, rats, and other vermin which may threaten to infest them must be destroyed. Any rich soil, besides being too costly, is unsuitable on account of the tendency of a flush of grass to produce a general and destructive dysentery. Many ordinary sheep-walks would do well for warrens, but are more profitable for sheep-feeding; and almost all sandy or other loose-soiled hills were formerly thought to be peculiarly suitable for them, but even these are now found, in most instances, to pay better when used in some other way. Rabbits in warrens are caught either with fold nets, or with spring nets, or with a peculiar kind of trap, or with the aid of the ferret; and rabbits in covers or hedge-rows, started and hunted out by dogs, are shot in the way of sport. The best time for bringing their fur to the market is from October till January; and the best time for shooting them is when snow lies on the ground.

Rabbits in natural burrows or in ill-enclosed warrens sometimes prove a great nuisance to farmers. "A correspondent in your paper," says a writer in the Irish Farmer's Journal, "enquires how he may prevent the rabbits from frequenting his land, or how he may stop them from burrowing, &c. Last autumn, I planted, that is dibbled, a field of wheat; and after it came up, I found the rabbits had eaten off the greater part of the outside of the land. Wishing to stop them, I bought some soot, and had it thinly strewed over those outsides where the rabbits came, and some refuse lime from the gas-works over some of the adjoining lands; and I do not think the rabbits have ever touched it since. Some gas tar poured into their holes, I have no doubt, would compel them to forsake the same."

The tame rabbit can be reared with little trouble and at very small expense. It will, of course, be kept only in situations where a proper market exists for it, or by families who wish it for their own use; but were it duly appreciated, and properly understood, it might, in many a place where it is at present unthought of, and by many a family of limited means, be made to furnish, readily and economically, a grateful change of nourishing and wholesome food. It is extremely delicate when used immediately after it has been suckled; and it becomes very agreeable when properly fed with hay, green plants, roots, farinaceous substances, and steamed potatoes through a period of about three months. But thorough attention must be given to proper feeding, to dryness, to cleanliness, and to ventilation. The boxes or compartments used for rabbits, and popularly termed hutches, should be placed on the top of one another round the sides of an airy room, or sufficiently sheltered division of an outhouse. Single hutches are suitable enough for males or for weaned young ones; but double hutches, or hutches with two divisions, the one for sleeping in and the other for feeding in, are requisite for the breeding females; and all the single hutches and feeding divisions of the double ones, should be furnished with troughs for containing the food. The female, except at a brief period six or eight weeks after she has brought forth, ought always to be kept completely inaccessible to the male; and whenever her time of accouchement approaches, she must be furnished with a little hay.

A method of keeping tame rabbits in a manner approaching the liberty and wildness of the warren, has been recommended as follows:—"In any part of the premises that may be considered

eligible, a stable yard for instance, let the earth be removed, 6 feet deep and 3 wide. A foot from this square hole, let another be dug of the same depth, and 4 feet wide,—the latter to be bricked all round, and divided from the smaller space by a brick partition, open at the bottom large enough to admit a full grown rabbit. Down this party wall an iron plate is to be slided at pleasure, by a rope from above. This forms the communication between the two apartments, the former of which, the smaller, we will call the warren, the latter, the trap. Light covers of wood, or even of tarred sailcloth, stretched and nailed on a frame of wood, are to be adapted to each space, either with hinges, fastened to a lower frame, or entirely moveable. The trap, or larger bricked compartment, is also the feeding place, into which not only garden vegetables may be thrown, but troughs containing bran and oats are to be let down, fastened to the ends of sticks of a convenient length, perhaps 4 feet. As soon as the stock of rabbits is placed in their future home, the animals will begin to burrow in the warren (the brick-work will prevent them from doing this in the other space); and when they are hungry, they will naturally pass through their door to obtain the food which will await them in the trap. The iron sliding door of communication will of course never be let down but for an express purpose,—the chief obviously being to catch and select them while they are assembled at their meal."

RABIES. See Hydrophobia.

RACE. A variety or breed of horses or cattle or other domesticated animals; also, a trial of speed between two or more animals, particularly between two or more horses. See the articles Racing and Horse.

RACEME. See Inflorescence.

RACEMIC ACID. A vegetable acid found readily in the grapes of certain districts, and probably occurring more or less in all grapes. It is nearly akin to tartaric acid, not only in being naturally associated with it, but in having a similar and even isomeric constitution.

RACHIS. The flexuous axis of the inflorescence of the grasses; also the petiole and midrib of the frond of ferns.

RACING. A trial of speed, under stringent conditions, and in the way of public gaming and amusement, between two or more trained racehorses. We have said enough respecting racehorses in the article Horse; we have not a word to say respecting the gaming and the general spirit of the English race-course except to denounce them as immoral; and we need not usurp the functions of the Racing Calendar in detailing the rules and practices of the turf, as nobody is likely to consult us for such information. We shall merely say that, if ever racing can be made to comport in any tolerable degree with right feeling or common sense, it must both renounce gaming and cruelty, and directly address itself to some useful purpose. "It must be obvious," says an able writer, who is very far from according with us in dislike to the thing itself, "that the practice of racing should be such as to encourage and promote the qualities desired to be perpetuated, and such as are of the greatest public value. Thus in Persia, continued speed being the object required, the race is protracted for several days, so as to be a severe test of endurance,—a quality of considerable importance in travelling from one part of the country to the other, and in transmitting expresses. On the contrary, in South America, where sudden speed is useful, and commonly called for in taking wild cattle, the race is exceedingly short. In these instances, the qualities sought to be encouraged are those of the greatest and most common use. So in England something besides speed being requisite, it should be the study of those possessing influence in these matters, to direct the public taste to the encouragement of qualities of national importance. Marshal Marmont judiciously observes on this topic, that 'Les encouragemens, les prix, les primes, devraient être calculés sur des épreuves applicables aux besoins des divers usages publics et domestiques et non pas être la recompense d'un mérite idéal.'" [Winter's Horse in Health and Disease.]

RACK. See Hay-Rack.

RADIATED FLOWERS. Composite flowers which have their outer florets in a radiated or stellate arrangement. They are distinguished by their form from discous flowers.

RADICLE. The part of the embryo of a plant which, in germination, descends through the soil and becomes the root. The name radicles is also given to the rootlets or radical fibres of a plant, to distinguish them from the main body of the root.

RADIOLA. A curious, little, annual, British plant, of the carnation order. It grows in sandy situations, and has a height of only one or two inches, and carries white flowers in July and August. It constitutes a genus of itself, and is called specifically *millegrana*, and popularly all-seed. Its generic name radiola signifies 'a little ray,' and alludes to the radiated form of its capsule.

RADISH,—botanically *Raphanus*. A genus of herbaceous plants, of the cruciferous order. It is nearly allied to the mustard genus, but may readily be distinguished from it by the form of its pods, which are many-celled or divided into several joints. Two species grow wild in Britain; two have been introduced from other countries; and several more are known. One of the indigenous species is noticed in the article Charlock; and one of the introduced species, in the article Landra. The other indigenous species, *Raphanus maritimus*, is a tap-rooted weed of the sea-coasts of Britain, commonly about 3 feet in height, and carrying yellow flowers from May till July.

The cultivated radish, *Raphanus sativus*, concentrates in itself the main interest of the genus. It is a native of China, and was introduced to Britain about the middle of the 16th century. Its root is annual and fusiform; its stem is about 3 feet high; its leaves are lyrate or sublyrate and rough; its flowers are whitish or tinged with purple, and naturally bloom from May till June; and its pods are uneven, tapering to a point, generally two-celled, and about as long as their stalks. It comprises many varieties, and is used for several purposes. The roots of most of the varieties are eaten raw, and highly relished, by all classes of the community, and serve the double purpose of gratifying the palate and acting as an antiscorbutic; the unripe seed-pods are used in pickles; the young green tops are used as small salading; and the seeds of several varieties, particularly those of *R. s. olifer*, are somewhat valuable for their oil. One classification of the varieties groups them into the small-rooted and the Spanish,—and distributes the former group into the round-rooted, the oblong turnip-rooted, and the oil-bearing,—and the latter group into the common, the black, the round, the grey, and the white; another groups them into the Spanish, the oblong, the turnip-rooted, and the long crooked,—and distributes the first of these groups into the black and the white,—the second into the red and the rose,—the third into the crimson, the early rose, the white, and the yellow,—and the fourth into the purple, the early scarlet frame, the purple-top white, the salmon-coloured, the scarlet short top, the white Italian, and Wood's early dwarf frame; another groups them into the fusiform-rooted spring varieties, the turnip-rooted spring varieties, and the autumn and winter varieties,—and distributes the first of these groups into the long white or white Italian, the white Russian, the twisted, the purple or short-topped, and the red-necked white,—the second into the white, the early white, the pink or crimson, the purple, and the yellow,—and the third into the late yellow, the round brown, the oblong brown, the white Spanish, the black Spanish, and the purple Spanish or large purple winter; and some other classifications, not only make different groupings from these, but include some other varieties or subvarieties, and give some of the same varieties other names. In a general view, the fusiform-rooted kinds are the best for main and early crops, the turnip-rooted kinds for secondary crops and change, and the Spanish kinds, and a new sort called the Breadalbane, for autumn and winter use.

The soil most suitable for the radish is a friable or porous and moderately fertile loam; and it should be dug to a good depth, and very finely pulverized. The situation, for early crops, must be warm and sheltered, yet, for both early and late ones, should be fully open to air and sunshine. Manure ought not to be applied in immediate preparation for the crop; or, if indispensable, must be in a finely divided state, and thoroughly intermixed with the soil. The seed may be sown in hotbeds for use in December, January, and February, and in the open ground for use at other seasons; and it may be sown monthly in winter, and fortnightly throughout spring and summer, and that of the Spanish kinds in July and August. The sowings in the open ground may be either broadcast on beds of 4 or 5 feet wide, or in drills of 3 inches asunder for the fusiform-rooted kinds, of 4 or 5 inches asunder for the turnip-rooted kinds, and of 6 or 8 inches asunder for the Spanish kinds; and they must, in every case, be thin and to the depth of about half an inch. The seedlings when so far up as to have each 5 or 6 leaves must be thinned,—the fusiform-rooted to distances of 3 inches, the turnip-rooted to 4, and the Spanish to 6. In moist hot weather, the spaces must be greater than these; and in dry weather, a watering ought to be given every night. Sowings and germinating crops which have to contend with frost, whether in the latter part of the year or in the early part, must be constantly protected by some sufficient covering; and rising crops, in the same predicament, must be similarly protected throughout the night and during every severe day, but fully exposed in mild or open weather. When roots come to be ready for use, the bed should be copiously watered 24 hours or so before they are drawn, and not watered again till after they are drawn; and they should be drawn early in the morning, and laid in a cool damp place till the hour when they are wanted for use. In November, the kinds which have been grown for winter use must be taken up during dry weather, and stored among sand for preservation; and the best of these kinds, if grown at sufficient widths, and if taken up and stored in this way, will retain their good quality till spring.

The seed of the hotbed crops must be sown on a layer of mould about 8 inches deep, and covered to the depth of half an inch with a sifting of mould. The proper time of sowing is the juncture immediately after the abatement of the violent heat of the hotbed. The plants will appear above the surface in less than eight days, and will be ready for use in the course of six weeks. Air must be given as long and freely as possible; but the glasses must always be closed toward evening, and a covering of mats or some other substance must, at all needful times, be given proportionately to the severity of the weather. The requisite temperature is from 50° to 70°; the distances of the plants from one another must not be less than two inches; and, at any time when the mould appears dry, a light watering must be given about noon. Crops raised in spring in a cold frame, with due protection, are two or three weeks earlier than contemporaneous and duly protected crops in the open ground.

Sowings for furnishing young green tops as small salads, should be made once a-week. Plants of any of the early or summer varieties intended to yield seed, should be selected from a main crop at the time of its greatest vigour, and taken up with the least possible injury to the roots, and dibbled in, quite down to the leaves, in rows at distances in every way of about 3 feet, and watered freely till they become established, and afterwards watered occasionally as the needs of their growth and the state of the weather may require. Plants of the Spanish or other late kinds intended to yield seed should either be raised from a special sowing in March, or transplanted in that month from a crop which has stood over the winter. Pods for pickling must be gathered while young and tender; and pods for seed, when they acquire a brown hue. Two varieties must not be raised for seed in the vicinity of each other; but every variety must be brought to seed with the same precautions against natural hybridizing which are necessary in the case of cabbages and borecoles. See the article Brassica.

Field crops of radishes are raised on the rich loamy soils of the Isle of Thanet and East Kent, for the supply of the seeds to the London market. "The radish seed is sown in furrows, about 10 inches apart, in a dry time of the month of March, at the rate of about 2 or 3 gallons per acre. As soon as the plants appear, every other row is cut up with a horse-hoe, leaving the rows 20 inches apart. When the plants get 2 or 3 rough leaves, they are hoed out in rows, and are then kept clean by repeated horse and hand hoeing, when necessary; leaving the plants at about 18 inches distance. The crop is seldom fit to reap till October, and is sometimes out in the fields until Christmas, without receiving injury from the wet weather, it being requisite to allow it much rain, in order to rot the pods and facilitate its thrashing. The produce is from 8 to 24 bushels per acre."

The oil radish, *R. s. olifer*, has a height of only from 6 to 24 inches, and is very much branched and spreading, and produces more seed pods than any of the common varieties. It is somewhat extensively grown in China for its oil; and has, for some time past, been cultivated in several parts of Continental Europe; and has been a good deal recommended as a general substitute for rape. But it does not seem to have been anywhere very successful in Europe; and it does best in countries, such as those upon the seaboard of the Mediterranean, where it can be sown in autumn and reaped in the end of spring or beginning of summer; and it is too tender to bear sowing in the fields of any part of Britain till after the disappearance of the frosts of spring. Its oil, too, though somewhat superior to that of rape, is more difficult of expression.

RADISH (Horse). See Horse Radish.

RAFFLESIA. A genus of wonderful, ornamental, tropical plants; nearly allied to the passion-flower and the pitcher-plants, but properly constituting an order of its own. Arnold's species, *R. Arnoldii*, is the most gigantic known flower in the world, and is all flower together, and yet is merely a parasite, growing on some crack of the root or stem of a vine or of some other vast climber, which are attached like cables to the largest trees of the tropical forests. It was discovered in 1818, in the Island of Sumatra, growing close to the ground under bushes, with a swarm of flies hovering over its nectary, and apparently laying their eggs in its substance. It is called by the natives krubut or the great flower, or ambum-ambum, wonder-wonder, or the flower of flowers. It has neither root, stem, nor leaves; yet, when full grown, it weighs of itself about 15 lbs., and has a breadth of upwards of 3 feet. It is dicœcious; and the male of it was brought to Britain soon after its discovery. Its first appearance is that of a round knob; and this, when cut through, exhibits the infant flower enveloped in numerous bracteal sheaths, which successively open and wither away as the flower enlarges until at the time of full expansion, very few remain, and have somewhat the appearance of a broken calyx. Three months elapse from the first appearance of the bud to the full expansion of the flower. The segments of the perianth are 5 in number, roundish, of a brick red colour, covered with protuberances of a yellowish white, and measure 12 inches from the base to the apex. About a foot intervenes from the insertion of one petal to that of the opposite. The nectary would hold 12 pints. The pistils are nearly as large as cow's horns. The female flower differs little in appearance from the male, except in wanting anthers; and, in its decay, it extricates seeds or spores, which are dispersed throughout its pulpy mass.—The Patma species, *R. Patma*, occurs in the south of Java, and varies in the diameter of its full-sized expansion from about 11 to about 25 inches, and is not dicœcious.

RAFNIA. A genus of ornamental, evergreen, yellow-flowered, Cape-of-Good-Hope plants, of the genista division of the leguminous order. Five or six species, chiefly shrubby and about 2 or 3 feet high, have been introduced to the greenhouses of Britain; and a number more are known. The best soil for the introduced ones is a sandy loam.

RAFT. A quantity of timber linked close together in such a manner as to be conveniently floated along a river or canal or lake.

RAFTER. A four-sided piece of timber used in roofing houses.

RAFTERING. Sawing logs of wood or planks of trees into rafters; also, the ploughing of one half of a grass field in such a way as to turn the grass side of each ploughed furrow on the land which is left unploughed. The raftering of land is practised chiefly in Wiltshire, and is a cheap and slovenly way of rendering loose land firm for

sowing, or of imitating the mechanical effects of sheep-folding. The operation is performed as early in autumn as the land can be wanted from pasturing; and the land, after undergoing it, lies untouched till near seed-time, and is then harrowed down and ploughed preparatorily to sowing.

RAG. See Rags.

RAGGED ROBBIN. The cuckoo-flower or *Lychnis flos-cuculi*. See Cuckoo-Flower.

RAG FALLOW. See Fallow.

RAGS. Torn and worn pieces of any kind of cloth. Linen rags, by means of the simple agency of sulphuric acid, yield more than half their weight of sugar; and both they and cotton rags form a very important commodity throughout Europe for the manufacture of paper.

Woollen rags are a valuable manure, particularly for hops, fruit-trees, and vines. They contain a very large proportion of albuminous matter, and minute portions of lime and silica, and traces of various salts. Wool, according to analysis by Scherer, comprises 50·653 per cent. of carbon, 7·029 of hydrogen, 17·71 of nitrogen, and 24·608 of oxygen and sulphur. Both woollen rags and the waste clippings of fleeces, therefore, are powerfully nutrimental to crops; and they decompose slowly in the soil, and attract and retain moisture, and generate a long course of appreciable heat, and form important elastic and soluble aliments for absorption by the spongioles; yet in dry seasons, and in the manner in which they are commonly used, they have been found to attract vermin, create dry mould, and entail a considerable amount of evil. The farmers of Kent and Berkshire and Oxfordshire, usually cut them by means of a chopper and block into shreds of about one or two inches square, and spread them on their fields by hand, out of a common seed basket; and when the rags are applied in this way, they serve suitably enough either as a top-dressing on young grasses, or as an inhumed manure so ploughed in with one furrow as not to be pulled above ground by the harrows. But, in general, they would do far better to be specially prepared. "An excellent preparation," says Mr. Donaldson in his Treatise on Manures, "has been effected by steeping them chopped in small pieces in privies or urine pits; and they may then be applied to any crops. When chopped small and laid in drills for turnips, potatoes, and beet, they failed by 30 per cent. against farm-yard dung. The barley and hay crops showed a difference for a time after brairding, as often happens with such manures, but none at the time of reaping. It was curious to observe the dark green colour of the artificial grasses during winter and spring, till the growth commenced, when the difference soon vanished." But one of the best ways of preparing woollen rags, so as to effect uniformity of distribution, and to make them speedily or duly available for the nutrition of crops, and to draw from them a sufficiently rapid supply of food during the vigorous or hungry period of the growth of quickly growing crops, is to cut them into pulp by the rag-cutting machinery of a paper-mill, and to run the pulp of them immediately into a heap of earth, and form it into a compost. The quantity of rags apportioned to any field or to an acre cannot at present be reduced to any rule, and will in practice be very much determined by the abundance and the expense of them as compared to those of other suitable manures. A full supply of them can seldom or never be had; though, when their value becomes better known, they will be more carefully collected, and will either fall in price or rise in demand. An extensive dealer in them informed Mr. Cuthbert Johnson, a number of years ago, that at least 20,000 tons were then annually consumed by the farmers of the South of England; and some writers allege that the average quantity in which they are applied amounts to about 13 cwt. per acre. "Twenty-five cwt. per acre of woollen rags," says Boussingault, "the cost of which in France may be about £3, has been found sufficient as manure for 3 years. The slowness with which wool decomposes, indeed, causes its action to be continued during 6 or 8 years. Twenty-five cwt. of woollen rags may be held equivalent to upwards of 40 tons of farm dung, which at the price of 5s. 10d. per ton, would cost £11 13s. 4d. At the end of 3 years, M. Delonchamps, an excellent practical farmer, gives his land a dressing of farm dung for 3 years more, when he returns to the wool. Sinclair says that they are best suited for dry and sandy or chalky soil, and this because they attract moisture. I have not found the fact to be so. In the very dry soil of a vineyard, manured with this article. I have found the pieces to decompose with extreme slowness, and the effect upon the vines for a very long time to be scarcely perceptible." See the article Hop.

RAGWORT. See Groundsel.

RAIL. See Corn-Crake and Water-Rail.

RAILING. See Paling.

RAIN. This meteorological phenomenon depends upon the formation and dissolution of clouds. The humidity suspended in the atmosphere is derived from the evaporation of water, partly from land, but chiefly from the vast expanse of the ocean. A surface of lake, of pasture, corn-field or forests supports a continual evaporation, augmented only by the dryness of the air, and the rapidity of its successive contacts. Even ploughed land will supply nearly as much moisture to the atmosphere as a sheet of water of equal dimensions. If the whole of the waters, which fall from the heavens, were to return again, the evaporation from the ground might be sufficient alone to maintain the perpetual circulation. But more than one third of all the rains and melted snows are carried by the rivers to the ocean, which must hence restore this continued waste. The air, in exhaling its watery

store, is rendered quite damp; but it may afterwards become dry, on being transported to a warmer situation. Such is the case with the sea-breeze, particularly in summer. It arrives on the shore cold and moist; but as it advances into the interior of the continent, it grows milder and drier. The moisture deposited by a body of air in minute globules, which remain suspended or subside slowly in the atmosphere, constitutes a *cloud*. When it comes near us, whether it hovers on the tops of the hills or spreads over the valleys, it receives the name of a *fog*. The production of rain has, from the earliest times, engaged the attention of philosophers; but it was reserved for Dr. James Hutton, of Edinburgh, to afford the true solution of the problem. His theory of rain was made known in 1787; since which period it has been greatly neglected by writers upon meteorology, until within a very few years. We shall now give an outline of Dr. Hutton's views. Air, in cooling, it is known, has the property of depositing the moisture it contains. But how, it may be asked, is it cooled in the free atmosphere, unless by the contact or commixture of a colder portion of the same fluid? Now the portion of air which is chilled must, in an equal degree, warm the other. If, in consequence of this mutual change of condition, the former be disposed to resign its moisture, the latter is more inclined to retain it; and, consequently, if such opposite effects were balanced, there could on the whole be no precipitation of moisture. The separation of moisture, on the mixing of two masses of damp air at different temperatures, would therefore prove, that the dissolving power of air suffers more diminution from losing part of the combined heat, than it acquires augmentation from gaining an equal measure of it; and, consequently, this power must, under equal accessions of heat, increase more slowly at first than it does afterwards, thus advancing always with accumulated celerity. The quantity of moisture which air can hold, thus increases in a much faster ratio than its temperature. This great principle in the economy of nature was traced by Dr. Hutton from indirect experience. It is the simplest of the accelerating kind, and perfectly agrees with the law of solution, which the hygrometer has established. Suppose equal bulks of air in a state of saturation, and at the different temperatures of 15 and 45 centesimal degrees, were intermixed; the compound arising from such union will evidently have the mean temperature of 30°. But since, at these temperatures, the one portion held 200 parts of humidity, and the other 800, the aggregate must contain 1,000 parts, or either half of it, 500; at the mean or resulting temperature, however, this portion is only capable of suspending 400 parts of humidity, and, consequently, the difference, or 100 parts, amounting to the two hundredth part of the whole weight of air, must be precipitated from the compound mass. In this example, it has been assumed that the portions of differently heated air were saturated with moisture before mixing; but it is only required that they should approximate to this condition. The effect, however, of simple commixture would, in most cases, be very small. To explain the actual phenomena, we must have recourse to the mutual operation of a chill and of a warm current driving swiftly in opposite directions, and continually mixing and shifting their surfaces. By this rapidity, a larger volume of the fluid is brought into contact in a given time. Suppose, for instance, the one current to have a temperature of 50°, and the other that of 70° Fahr.; the blending surfaces will therefore assume the mean temperature of 60°. Consequently the two streams throw together 200 and 334·2 parts of moisture, making 567·1 parts for the compound, which, at its actual temperature, can hold only 258·6 parts; the difference, or 8·6 parts, forms the measure of precipitation, corresponding to the 2325th of the whole weight of the commixed air. It would thus require a column of air 30 miles in length to furnish, over a given spot, and in the space of an hour, a deposit of moisture equal to the height of an inch. If the sum of the opposite velocities amounted to 60 miles an hour, and the intermingling influence extended but to a quarter of an inch at the grazing surfaces, there would still, on this supposition, be produced, in the same time, a fall of rain reaching to half an inch in altitude. These quantities come within the limits of probability, and agree sufficiently with experience and observation. But in the higher temperatures, though the difference of the heat between the opposite strata of air should remain the same, the measure of aqueous precipitation is greatly increased. Thus, while the mixture of equal masses of air, at the temperatures of 40° and 60°, is only 6·6, that from a like mixture of 80° and 100° amounts to 19. This result is entirely conformable to observation, for showers are most copious during hot weather and in the tropical climates. The quantity of rain precipitated from the atmosphere, thus depends upon a variety of circumstances,—on the previous dampness of the commixed portions of the fluid,—their difference of heat,—the elevation of their mean temperature, and the extent of the combination which takes place. When the deposition is slow, the very minute aqueous globules remain suspended, and form clouds; but if it be rapid and copious, those particles conglomerate, and produce, according to the temperature of the medium through which they descend, rain, mist, snow, or hail. The foregoing theory tallies precisely with what we experience in the connexion of rain with the variable nature of the winds. Steady dry weather is always accompanied by a steady direction of the wind; whereas, in rainy weather, the winds are unsteady and variable. The heavy rains that fall in India always take place during the shift-

ing of the monsoons; and while they last, the winds are always veering.—The annual quantity of rain is greatest at the equator, and gradually diminishes as we approach the pole. This will be evident from the following table, showing the annual depth of rain in different latitudes.

	Lat. N.	Fall of Rain.
Grenada,	12°	126 inches.
Cape François,	19° 46′	120 "
Calcutta,	22° 23′	81 "
Rome,	41° 54′	39 "
England,	50° to 55°	31 "
Petersburg,	59° 16′	16 "
Uleaborg,	65° 1′	13½ "

On the contrary, the number of rainy days is smallest at the equator, and increases in proportion to the distance from it. From north latitude 12° to 43° the mean number of rainy days is 78.

From 43° to 46° the mean number is	103
" 46° " 50° " " " "	134
" 50° " 60° " " " "	161

Hence it is obvious that the rain falls in very heavy showers in warm climates, and that it becomes more and more gentle as we advance towards the pole. Consequently, in hot climates, the air must be much less loaded with moisture, and the rate of evaporation much greater than in cold climates. For when rain falls very heavy, a great portion of it runs off by the surface, and flows into the sea. But this happens to a much less extent when the fall of rain is more gentle.

RAIN-GAUGE, or PLUVIOMETER. A machine for measuring the quantity of rain that falls. There are various kinds of rain-gauges: one of the best is a hollow cylinder, having within it a cork-ball attached to a wooden stem, which passes through a small opening at the top, on which is placed a large funnel. When this instrument is placed in the open air, in a free place, the rain that falls within the circumference of the funnel will run down into the cylinder, and cause the cork to float; and the quantity of water in the cylinder may be seen by the height to which the stem of the float is raised. The stem of the float is so graduated as to show, by its divisions, the number of perpendicular inches of water which fell on the surface of the earth since the last observation. It is hardly necessary to observe that, after every observation, the cylinder must be emptied. A very simple rain-guage, and one which answers all practical purposes, consists of a copper funnel, the area of whose opening is exactly ten square inches. This funnel is fixed in a bottle, and the quantity of rain caught is ascertained by multiplying the weight in ounces by 173, which gives the depth in inches and parts of an inch. In fixing these gauges, care must be taken that the rain may have free access to them. Hence the tops of buildings are usually the best places. When quantities of rain, collected in them at different places, are compared, the instruments ought to be fixed at the same heights above the ground at both places, because, at different heights, the quantities are always different, even at the same place.

RAJANIA. A genus of tropical plants, of the yam family. Three species, all summer-blooming climbers, with herbaceous coloured flowers, and varying in height from 7 to 24 feet, have been introduced to Britain; but are interesting only to botanists. The name was formed in honour of the distinguished British naturalist Ray.

RAKE. A toothed implement for gathering hay, gleaning stubbles, pulverizing small beds of soil, covering small garden seeds, and several other kindred purposes.

The corn-rake varies in size and structure in different counties; but, in most cases, is a more or less simple drag-implement with iron teeth. "The head of the corn-rake," says an article in the Quarterly Journal of Agriculture on Reaping with the Scythe, "should be made of fine ash as light as possible, but strong enough to bear the driving in of a number of iron teeth; and it should be at least 5 feet in length, and feruled with iron at both ends. The teeth should be 7 inches in length, and 4 inches apart, and so curved at their point as that the weight of the rake may rest upon the curve, with their points free of the ground, when the rake is held in a working position. The points of the teeth should be thin and broad. The shank of the rake may be of light fir, and fully 6 feet in length. An iron rod passing from the shank on each side to the head, will prevent the latter being twisted out of its post. A short handle, like the left handle of the scythe, and fastened at a convenient spot on the shank with an iron wedge, will facilitate the passage of the rake over the ground."

"The drag-rake, in its simplest form," says Mr. Ransome, "is merely a long cross head, with a row of teeth placed in it; in some these are straight; they are, however, generally bent, with their points projecting forward. A very excellent and light implement, having the teeth of steel, and made with screws, so as to admit of being easily replaced in case of accident, is well known as Badgley's improved drag-rake. These rakes have, from time to time, increased in length and weight, till they became too large to be balanced by the hand. Two small wooden wheels were then added, which rendered them manageable by women or boys. Further addition having been made to them, they are now sufficiently strong to be worked by a horse. Used on fallows when foul, to remove the couch grass, they act as a harrow, to get together the rubbish, or in harvest time they act as a rake to collect the loose corn which may have escaped from the scythe or sickle. In order to clear them readily, there are different contrivances; one of the most simple and efficient of which is such, that by lifting the handle the teeth are brought between two iron bars, which constitute part of the frame, by which means all the rubbish is stripped off from the teeth of the rake."

The hand hay-rake, and the most important kinds of horse-rake for either hay or corn, are noticed in the article HAY-RAKE.—The garden iron rake is a very simple yet very important implement, of various sizes.—The drill rake is a large-headed rake with triangular teeth, like small coulters, set at 6 or 9 or 12 inches' distance according to circumstances; and is drawn across prepared beds or ridges to form drills for planting maize or saffron, or for sowing field crops of onions, carrots, or similar small-seeded crops.—The lawn or daisy rake has teeth closely set to one another, and sharpened on both edges like lancets; and is used for tearing off the buds and flower-heads of daisies and other intruding plants on lawns.

RAKING, or BACK-RAKING. The removing of hard fœces from the rectum of the horse with the hand. It is a useful operation in cases of constipation accompanying fever or inflammation; and ought, in all such cases, to precede the injection of clysters. A boy with oiled hand and arm performs it best; but he must be a steady lad, and should proceed slowly and cautiously.

RAM. An entire male sheep,—called in Scotland a tup. Rams, except at particular seasons, must be kept constantly separate from the rest of sheep stock, and even ought not to be within reach of their smell. See the articles SHEEP and BREEDING.

RAMOON-TREE,—botanically *Trophis*. A genus of ornamental, tropical, ligneous plants, of the wild olive tree family. Two species, both green-flowered evergreens of between 20 and 30 feet in height, loving a soil of loamy peat and propagable from cuttings, have been introduced to British collections; and some others are known. They are of some use to cattle in their native country, and hence received the name of trophis, which signifies fodder.

RAMPION,—botanically *Phyteuma*. A genus of ornamental herbaceous plants, of the bellflower order. One species grows wild in Britain; about 30 species have been introduced from other countries; and several more are known. The great majority are hardy and perennial-rooted, and have a height of between 6 and 24 inches, and carry blue or violet flowers in summer, and love a soil of peaty loam, and are propagated by division of the root, and do well for either rockwork or the flower-border or small pots.

The indigenous species, or round-headed rampion, *Phyteuma orbiculare*, occurs on pastures and on the sides of roads in some of the chalk districts of England, but is rare. Its root is woody and long, and divided at the crown; its stem is solitary, simple, smooth, angular, leafy, and commonly about a foot in height; its radical leaves are cordate or elliptico-lanceolate, and its cauline ones crenate, and all smooth and reticulately veined; and its flowers come out in a round head, with several leafy bracts, and are sessile, inodorous, and numerous, and have a violet or exceedingly brilliant deep blue colour, and bloom from June till August.

The spiked rampion, *Phyteuma spicatum*, has sometimes been used as an article of food. It is a native of Continental Europe, and was introduced to Britain toward the close of the 16th century. It differs from all the other species in having white-coloured flowers; and it usually attains a height of about two feet, and blooms from June till August.

RAMPION (GERMAN). See ŒNANTHE.

RAMPIONS, or RAMPION BELLFLOWER,—botanically *Campanula Rapunculus*. An indigenous, biennial, ornamental, and culinary plant, of the bellflower genus. See the article BELLFLOWER. It was formerly cultivated for sake of its esculent, tuberous root, but has, in a chief degree, ceased to be in request. It may, when wanted, be raised from seed sown in March or April, on a shady border, either broadcast or in drills 6 inches apart. The young plants must be thinned out to distances of 6 inches from one another in May; and the root will be fit to draw in the following autumn, winter, and spring.

RANDIA. A genus of ornamental, evergreen, white-flowered, tropical shrubs, of the madder tribe. Seven or eight species, varying in height from 5 to 15 feet, have been introduced to the hothouses of Britain; and all love a soil of loamy peat, and are propagated from cuttings. The prickly species, *R. aculeata*—called by some botanists *Gardenia randia*—is the tallest and one of the best known of the introduced species, and was brought to Britain upwards of a century ago from the West Indies. The stem is shrubby, and has a whitish bark, and rises to the height of from 10 to 15 feet; the branches come out oppositely from the sides of the stem, in such a way that each pair crosses the other; the leaves come out by pairs on short footstalks, and are thick, a little indented at the top, and about an inch long and three-fourths of an inch broad; two short spines stand oppositely at the joints immediately under the leaves; the flowers come out from the side of the branches, and are small, tubulous, and five-parted, and bloom from May till September; and the fruit are oval berries, about the size of marbles, with a brittle shell under a thin skin, and containing many compressed seeds within a black pulp.

RANUNCULUS. A large genus of ornamental, herbaceous, exogenous plants, constituting the type of the order Ranunculaceæ. This order stands at the head of the dichlamydeous division of exogens, or those which have both a calyx and a corolla,—of the thalamiflorous subdivision, or those which have the petals and the stamens inserted into the receptacle,—and of the first section of that subdivision, or those which have the carpels numerous, or the stamens opposite the petals. It at present comprises, within the gardens and botanical collections of Britain, 8

or 9 stove species, about 20 greenhouse species, nearly 50 hardy ligneous species, and about 600 hardy herbaceous species; and it is divided into five tribes,—the Ranunculeæ, the Anemoneæ, the Helleboreæ, the Clematideæ, and the Pæoniaceæ, comprising respectively four, six, eleven, three, and five genera. It naturally ranges over by far the greater part of the world; but is particularly abundant throughout most of Europe, and in some of the temperate parts of Asia. Its genera differ very widely from one another in external appearance, and in many of the most obvious botanical characters, yet are all at one in the essential characters of their fructification. The majority are objects of great interest to gardeners and florists; and many rank among the most brilliant and showy and beautiful flowering plants in the world; and a large number occur on the open border of every tolerably good flower-garden, or sometimes on even the most common cottage parterres. All, however, are as remarkable for their dangerous acridity as for their pleasing beauteousness; and not a few are very powerfully caustic and venomous. The crowfoots of our European pastures and the *Anemone trilobata* and *triternata* of those of South America, are well known poisons of cattle. The foliage of the acrid crowfoot is used by the inhabitants of Iceland for making blistering plasters; and that of some species of Clematis is supposed to afford the means employed by beggars of producing artificial ulcers. Some of the aconites, the crowfoots, and the hellebores figure in the pharmacopœias as very powerful medicines; and several of them are known also in the arts, either furtively or otherwise, as mightily active or mischievous agents. A species of nigella, too, is celebrated in ancient housewifery for its aromatic seeds, which were used in the same way as pepper now is; and a species of larkspur is said to be an ingredient in certain French cosmetics which act destructively on the surface of the skin. Yet the peculiar active principle of the Ranunculaceæ is of so very singular a nature as to be destructible only or at least chiefly by air and water; it is neither acidous nor alkaline; it acquires increase of power from mixation with sugar, honey, wine, alcohol, or acids; and it is so very volatile, or passes so very facilely into the atmosphere or into water, that, in most instances, simple drying in the air or simple infusing in water is sufficient to expel it. The principal medicinal properties of the officinal Ranunculaceæ are diuretic, sedative, emmenagogue, and violently cathartic or drastic.

The genus ranunculus is very broadly distinguished by the physical characteristics of the order, both floral and chemical. The genera which it represents as the type of the tribe Ranunculeæ are ranunculus, myosurus, ficaria, and ceratocephalus. Its calyx is five-leaved; its corolla is five-petalled, with a melliferous pore within the claws; and its seeds are naked. Seventeen species of it grow wild in Britain; upwards of 50 species have been introduced from other countries; and about 100 other species are known. Most of its species naturally inhabit moist places; and, in fantastic allusion to this circumstance, it obtained the name of ranunculus, from a Latin word signifying a frog. One very large subgenus of it consists principally of erect terrestrial perennials, and has fibrous roots, white or yellow flowers, and smooth, ovate, roundish carpels, disposed into a round head; another and much smaller subgenus, consists of terrestrial perennials, and has grumose roots, generally though not universally yellow flowers, and smooth carpels, disposed into a close spike; a third and still smaller subgenus consists of annuals, and has yellow flowers, and rough, tuberculous, or prickly carpels; a fourth and yet smaller subgenus consists of aquatic perennials, and has white petals, a yellow claw marked with a nectariferous hollow, and a transversely striated pericarp; and a fifth and smallest subgenus consists of terrestrial perennials, and has grumose roots, yellow flowers, and smooth subglobose carpels. All the species in Britain are herbaceous; all, except two or three, are hardy; most have a height of between 4 and 15 inches; very many deserve a place on the flower-border; some are among the most common of our wild flowers; and the majority thrive in any common soil, and are readily propagated by radical division. The indigenous species are noticed in the article Crowfoot; and only one of the exotic species, incomparably the most brilliant, and every way worthy to concenterate in itself the main floral interest of the whole genus, must form the subject of the sequel of the present article.

The Asiatic or common garden ranunculus, *R. asiaticus*, was introduced to Britain from the Levant toward the close of the 16th century. It is often called par excellence the ranunculus, as if there were no other; and it comprises a countless number of varieties and subvarieties, with double and semi-double flowers, of every hue from a creamy white to the deepest crimson, nearly approaching to black, and, in many instances, so beautifully variegated with streaks and dots and different markings as to rival the most superb picotees and carnations. Its root is grumose; its stem or stems are commonly about 9 inches high; and its leaves are trifoliate and twice trifoliate, with cut and trifid lobes. Two typal or fundamental forms of its multitudes of varieties occur,—the blood-coloured, *R. a. sanguineus*, with scarlet flowers, and originally from Syria,—and the fine-lobed, *R. a. tenuilobus*, with white flowers, and originally from Greece; but the varieties or subvarieties themselves cannot easily be classified, and almost defy enumeration. Any variety, if well treated, is supposed to be capable of lasting during from 30 to 40 years; but few or none, no matter how well treated, live vigorously or even live at all be-

yond that period; and some, or perhaps most, are liable to a very speedy extinction by bad keeping, hot manuring, or other improper treatment. Lamentations have for many years past prevailed, that the ranunculus has sadly degenerated, and has become exceedingly difficult of culture, and deplorably liable to failure; and nostrums many and intricate have been propounded by all sorts of amateurs for reviving it, or for obtaining sure and beauteous blooms, by means of curious manuring or of novel methods of culture. But if the varieties be new enough, and the time of planting suitable enough, and the soil consolidated and cool enough, and at the same time free from stimulating or unduly strong manure, no apprehension need be entertained that blooms of this most gorgeous flower will be obtained as good and certain as before the cry of degeneracy was raised.

The following directions for cultivating the ranunculus were transmitted to England a few years ago by M. Tripet le Blanc of Paris, one of the best ranunculus growers in France: and are perhaps as good as any which can be given:—The bed, which should be made in November or December, need not be more than a foot deep, and it should have an eastern exposure. The soil should be equal parts of fresh turfy loam and old cow-dung, or thoroughly rotten leaves, and these should be well mixed together by turning the mass over several times with the spade. The bed should be raised 3 or 4 inches above the level of the walks, to allow for its sinking. In the first week of February the tubers are to be planted, when strings should be stretched across the bed in slanting lines, 4 inches apart, so as to intersect each other like network; and drills should be formed under the strings an inch and a half deep. The tubers should then be put into the ground, one being planted at every point where the lines meet, and the earth should be drawn over them. Care should be taken never to cover the tubers more than an inch and a half deep; and it is better for the covering to be less rather than more. The tubers should be planted with their claws downwards, and the beds should be regularly watered whenever the weather is dry. The advantage of making the bed in November, and not working it at all when the tubers are planted in February, is that the soil has had time to settle, so as to afford a firm bed, which is advantageous, as the ranunculus never thrives in a loose soil; and by planting the roots in spring, they are saved from the danger of injury from cold and wet during winter. In England the bed is generally made two feet deep, and a layer of two years' old cow-dung, 6 or 8 inches deep, is placed at the bottom, the bed being filled up, and raised about 5 inches above the surface, with a fresh and strong loam, and the roots are planted in November, covering them 10 or 15 inches thick with straw during the frosty weather."

IV.

RAPE. Several species and varieties of cruciferous plants, of the turnip and cabbage genus, cultivated for the expression of oil, the feeding of cattle, and some other economical purposes.

Kinds of Rape.—The summer rape, cole, colsa, colza, or wild navew culsat, *Brassica campestris oleifera*, is noticed in the article Cole. The name of summer rape, given to this kind, refers to its arriving earlier at maturity than the common or winter rape, and also alludes to its being less capable of withstanding severe winters, and therefore more suitable to be grown for a summer or autumn crop than for a spring one.

The common rape or winter-rape or cole-seed, *Brassica napus*, occurs in a wild state in ditches and banks and borders of corn-fields of some parts of England. Its root is biennial, tapering, woody, and hard; its stem commonly attains a height of about two feet; its leaves are smooth, glaucous, and thickish or somewhat fleshy; its radical leaves are lyrate; its cauline leaves are clasping, notched, and pinnatifid; its flowers are yellow, and naturally bloom in May; and its seeds are similar to those of the Swedish turnip, and are sometimes smaller and sometimes larger than those of the summer rape, and are much controlled in size by the influences of soil and culture. This plant, in a growing state, is most readily distinguished from the summer rape by the smoothness of its leaves, and the comparatively deep and obscure yellowness of its flowers. But three very distinct varieties of it are in cultivation,—the oil-bearing, the greater, and the esculent, *B. n. oleiferus*, *B. n. major*, and *B. n. esculentus*,—the first and the second field plants, for oil and rape-cake and fodder, and the third a garden plant, for salads and other culinary purposes; and three permanent subvarieties of the last, also, are in cultivation,—the white, the yellow, and the blackish, *B. n. e. albus*, *B. n. e. flavus*, and *B. n. e. nigricans*. The greater variety, *B. n. major*, has comparatively large leaves, and is much cultivated in Alsace, and deserves special attention from farmers who raise the rape plant for fodder.

The early rape, annual rape, smooth-leaved summer rape, or early kohl-reps, *Brassica præcox*, is a native of Continental Europe, and was introduced to Britain in 1812. Its root is annual; its stem is about two feet high; and its stem-leaves are more lyrate, and its seed-pods more erect, than those of the common rape. It produces a smaller amount of herbage, and is less oleiferous, and has less power of resisting frost, than the field varieties of the common rape; yet, in consequence of its running to seed much sooner than these varieties, it might probably be found to succeed corn-crops with more advantage than they in Scotland and the northern parts of England.

The turnip rape or rough-leaved summer rape, *Brassica rapa*, occurs in a wild state in the corn-fields of some parts of England. It may be re-

garded as either the original and normal form of the common turnip, or as a group of all the varieties or subvarieties of that species which have fusiform roots; and it is either annual or biennial according to the season of the year in which it is sown. Its root is comparatively small and hard; its stem is about two feet high; its radical leaves are lyrate and vivid green, and have none whatever of the glaucous bloom which distinguishes the preceding kinds of rape and the many varieties of cabbage; and its cauline leaves are slightly glaucous and quite or nearly smooth, —and the lower ones are generally lobed or cut, and the upper ones almost entire.

The elongated or Hungarian rape, *Brassica elongata*, is a native of Hungary, and was introduced to Britain in 1801. Its root is biennial; its stem is smooth and between 3 and 4 feet high; its radical leaves are stalked, pinnatifid, sinuate, and hispid; its upper leaves are stalked, toothed, and smooth; its flowers are yellow and naturally bloom in May and June; and its pods are raised on short pedicels above the receptacle. This rape produces a smaller bulk of foliage than the summer and the winter rapes, and therefore is less adapted to be grown for forage; but it is said to yield a much larger quantity of seeds, and it is cultivated on account of these in its native country.

Garden Cultivation of Rape.—Rape, as a salad herb to be gathered in the seed-leaves, may be sown at any time of the year when it is wanted, and must be raised, in a separate bed, in the same manner as mustard and garden cress. Plants intended for seed should be selected from a sowing made in the latter part of June or in July, and must be thinned out to distances of about 15 or 18 inches; and they will bloom in May and June of next year, and mature their seeds in July and August. But due precaution must be used that no other brassica is going to seed in their neighbourhood, else they may egregiously fail to propagate their true or typal character. See the article Brassica. The ripe plants, too, should be carefully cut and laid upon cloths to dry, or they are very liable to shed their seeds.

A variety of rape, called the edible-rooted, may be cultivated in the garden for the sake of its root. It has long been cultivated on the Continent, and has been known for many years to a few persons in Britain, and is recommended to general notice in the Transactions of the London Horticultural Society. Its root is white, and carrot-shaped and about the size of the middle-finger, and very thin-skinned; and it has a much more delicate flavour than the turnip, and is cooked in the same manner as that root, except that it is only scraped and not peeled. It is cultivated in the same way as the turnip; but it requires no manure, and may be produced at almost any period of the year. Any soil of a light and poor kind, especially if decidedly silicious, is very suitable for it; and a richly manured soil will cause it to grow much larger, but will correspondingly impair its sweetness and delicacy. The main crops may be sown from the middle of June till the end of August, and will afford supplies of the root till April; a secondary crop may be sown in the latter part of October, to afford supplies in April and May; and crops may be sown on a warm border in January and February,—and again, on a moist north border from the latter part of March till May,—to keep up a succession of supplies throughout spring and summer. But the winter-growing crops are precarious; and the spring and summer-growing crops, from the time of sowing till they get three or four leaves, must be regularly watered in dry weather. Plants intended for seed must be selected in February or March, and either transplanted to distances of two feet from one another, or thinned out and left standing at these distances; and the ground around them must be kept clear of weeds and repeatedly hoed.

Field Cultivation of Rape.—The field rapes most suitable for being fed off with sheep, or for the soiling of cattle, occupy the same place in a regular rotation as the turnip or the potato, and serve excellently, in the former case, as a first crop on newly reclaimed land or on broken-up old grass land, and are also a valuable substitute for the turnip on arable lands which are too wet and heavy for that root. They succeed on most kinds of soil, and do well for a change upon ordinary or prime turnip soils, but are most partial to strong alluvial loams, to rich clays, and to lands of firm and good quality which have been long in grass. If grown on poor land, indeed,—especially if allowed to stand too thick,—rape has a small and woody stem, and is liable to be mildewed, and will generally be disrelished by stock and unprofitable to the owner; but when grown on clean and well-tilled land, and when properly cultivated,—and especially when rightly raised on well-conditioned aluminous soils,—it is generally luxuriant, and has a succulent stem and a sapid foliage which all sheep relish, and excels most field plants in escaping the attacks of insects and fungi, and in resisting the vicissitudes of the weather.

The cultivation of rape as an herbage plant on lands already under tillage differs little from that of the turnip. The land should be cleared of weeds and minutely pulverized by repeated ploughings and harrowings. On light soils, in the absence of farm-yard manure, bone dust may be advantageously employed, the quantity being the same as for a turnip crop. When rape is sown for the purpose of being eaten off with sheep, both the broadcast and drill systems are adopted; but when intended to be cut for feeding cows or other cattle in the house, the drill system is preferred. In every case, however, the drill system is preferable, as admitting the operations of hoeing and weeding to be performed with much greater facility and ex-

pedition. When sown in drills, from 3 to 4 pounds of seed per acre will be sufficient; and when broadcast, from 8 to 10 will be necessary. The time of sowing is from the middle of July till the middle of August. Rape succeeds well by being transplanted. By taking advantage of this property two crops may be got off the land in a season. For this purpose the seed is sown in beds in the garden, or in any other convenient spot at the usual time, and planted out as soon as possible after the grain harvest is secured; but this plan can only be adopted where the land is dry and where a green crop is to succeed. The stubble will be sufficiently pulverized under ordinary circumstances by a single ploughing and harrowing, and the plants may be drilled in rows 18 inches apart,—6 inches in the row, or narrower, according to the lateness of the season of planting and the quality of the soil. The method of transplanting rape in the Netherlands, where it is extensively cultivated, is to lay the plants at the regular distances on the newly turned up furrows in ploughing, and they are covered by the next furrow, and so on till all is planted. This plan has been partially introduced into England and Ireland; but planting by the dibble is to be preferred, as any advantage gained in the saving of time in the Flemish mode is more than counterbalanced by the loose and insecure way in which the plants are necessarily deposited. It cannot be expected that the crop under these circumstances will be as luxuriant as when sown in a proper season and the growth not checked by transplanting. This method of growing it is valuable only as securing a crop when the land would otherwise be unproductive; and if it be consumed on the land, a valuable and permanent improvement will be effected. The after cultivation in any case is the same as that of the turnip, and consists in weeding, hoeing, and thinning.

The crop may be cut down and given to cattle in the stalls, and a second cutting will be produced; but the better method of consumption seems to be to eat it down occasionally, with sheep on the land. The crop is commonly fed off at intervals from the beginning of November, until the middle of April, being valuable at the former period for fattening ewes, and at the latter for supporting ewes and lambs. Rape with a thick stem and in a luxuriant state is eaten with great greed and high relish by all sheep, and very rapidly fattens them; and, on good land, it may, in most instances, be readily worked or coaxed into this state by the very free use of the horse-hoe. Pithy, succulent, strong stems, in fact, are evidently better liked by sheep than the foliage, and may therefore be supposed to contain more nourishment, or at any rate to possess high adaptation to healthy and vigorous winter feeding. Some farmers even raise rape for the use of stock throughout a large portion of autumn, and obtain a regular succession of it by means of three several sowings between the middle of May and the end of June, and usually put their sheep upon it about three months after it has been sown, and afterwards sow the land with winter wheat. A considerable quantity of the very best food is thus produced during a period when it is greatly wanted, that is, from the time when the freshness of the clover and the grass leys is on the decline till the time when the turnips become fully grown; and this is considered equally valuable for the lambs when taken from the ewes, and for the shearing wether sheep 18 months old, which at that period are nearly fat and require food of the most nutritious kind.

Any land which has been cropped with winter rape, and fed off in winter or in spring with sheep, provided due culture has been given and no extraordinary wetness of weather have prevailed, is in a state of very high amelioration. It has lost absolutely nothing by the crop; and it has gained a great deal by the fallowing agencies of the culture, by the fixation of atmospheric gases, by the treading of the sheep, and by the deposition of their excrements. "Whatever be the succeeding crop," remarks Mr. Rham, "it cannot fail to be productive; and if the land is not clean, the farmer must have neglected the double opportunity of destroying weeds in the preceding summer and in the early part of spring. If the rape, supposing it to have been sown about the beginning or middle of August, be fed off in time, it may be succeeded by barley or oats with clover or grass seeds, or potatoes, if the soil is not too wet. Thus, no crop will be lost, and the rape will have been a clear addition to the produce of the land." Even land which has been cropped with summer rape, and fed off with sheep in autumn, is, in some cases, as much improved by the process, and in a state of as high preparation for the immediately succeeding crop of wheat, as if it had been summer-fallowed; yet, in wet seasons, and under excessive poaching from the feet of the sheep, especially in cases where the soil is decidedly argillaceous, it is always more unfit for wheat, and will yield a considerably smaller or inferior produce of it, than if it had been summer-fallowed. The substitution of fed-off rape for summer-fallow, therefore, ought to be done with caution, and only in certain circumstances; though it has sometimes been so successful, as besides affording a clear gain of the whole rape crop, and yielding the great convenience of a timely and valuable supply of sheep-food, to render very inferior clay soils productive of excellent crops of wheat.

A main excellence of rape as a forage crop, viewed with comprehension of the several varieties of the plant and of their wide range of adaptation to soil and season, is its capacity to supplement or substitute any green or fallow part of any ordinary rotation. It may be sown in spring, in summer, or in autumn,—in preparation for a spring crop or in preparation for a

winter one,—at the commencement of a course of tillage in breaking up from lea, or at the close of a course of tillage in returning to lea,—as either a substitutionary crop, or an intermediate crop, or a principal one,—and either only once at a time, or twice or oftener repeated. When land cannot be prepared in sufficient time for the turnip, it is yet ready for a crop of rape; when land is in too ungenial a condition for some other intended green crop, it may be in a suitable enough condition for rape; when land has been prepared for summer-fallow, yet is intended to be reserved for oats or barley in the following spring, it may be cropped in the intermediate time with rape; when land has been under early pease or under potatoes, and is not fit to be sown with winter wheat, it may be cropped with winter rape; and even, in many instances, when land is in ordinary rotation of alternate white and green crops, it may be advantageously sown with rape upon the ploughed stubble, and eaten off with sheep in March and the early part of April. An experiment was tried, nearly 20 years ago, at Netherby in Cumberland, of sowing in July 120 acres of prime loamy land with rape in the laying down of permanent pasture. The ground was thoroughly cleaned and limed; the rape and the grass seeds were sown together; and, as soon as the rape arrived at the proper stage of maturity, it was eaten off by sheep. A report of the experiment 8 years after says that it succeeded, and that the land was then the best pasture in the country.

The cultivation of rape for the production of oil is a widely different affair from the cultivation of it as a forage plant. The most suitable varieties of it, as we showed in a former section, are different; and the effects upon the land are so exhausting, that the rape must take the place of a white crop in a rotation, and must not be repeated sooner than after an interval of 5 or 6 years. But it is not suited to the coldness and moisture of the west coast of England and of most parts of Ireland; and it commonly yields so slender or precarious a compensation in even the most favourable parts of Britain, as to be suitable only in extraordinary circumstances or as an occasional crop. In the fens of Lincolnshire and Cambridgeshire, as a first crop on broken up land which has been long in grass and is of prime quality, it usually yields so great a produce as from 40 to 50 bushels per acre of clean seed, and is generally found to be highly or sufficiently compensating; but on similar soils in other circumstances, or as a substitute for a white crop in the course of a rotation, it sometimes or often does not yield more than one-half of that produce, and is there, of course, of correspondingly small value. It may be sown, according to the variety and the situation, from the end of May till the end of August; it may be sown broadcast at the rate of half a peck of seed per acre, but will do much better to be drilled; it should receive the same after-culture as when intended for a forage crop until the season of its passing into flower and seed; and if very luxuriant, it may more than once be slightly pastured by lambs when they are first taken from the ewes. The crop must not be cut till fully ripe, or about the month of June; and it should be cut while the dew is on it, and moved as little and gently as possible. It so easily sheds its seeds in consequence of the lower pods being ready to burst before the upper ones are full, that, if not very carefully managed, especially in unfavourable weather, a considerable portion of the produce will be lost; and, if the state of the weather will at all permit, it ought at once and promptly to be thrashed out in the field. In some parts of the Continent, where an oil-mill exists on the farm, the seed is conveyed thither and bruised immediately after being thrashed; but in England, it is generally spread out on the floor of a granary, and frequently turned over, till it become dry, and is then sold to the crushers who express the oil. The straw is often burned in the field; but ought always to be carried to the farm-yard and used for fodder and litter. The smaller twigs or branches are greedily eaten by either sheep or cattle or horses; and the thicker portions of the stems, or such parts of the entire straw as remain after being picked over by the cattle, are readily converted in the form of litter or with the aid of swine into valuable manure.—*Lawson's Agriculturist's Manual.—Rham's Dictionary of the Farm.—Knowledge Society's Outlines of Flemish Husbandry. — Knowledge Society's Reports on Select Farms.—Communications to the Board of Agriculture.—Marshall's County Reports.—Irish Farmer's Journal.—The Gardener's Gazette. — Mill's Husbandry. — Dickson's Practical Husbandry.—Transactions of the Horticultural Society.—Mawe. Johnson.—Doyle.—Low.*

RAPE CAKE, or Rape Dust. The refuse of rape seeds after the expression of the oil. It originally forms a hard cake, but can at any time be readily reduced to powder. It is used on the Continent for feeding cows and pigs, in the same manner as linseed cake; and is much employed, both on the Continent and in Britain, as a rich or special manure. Large quantities of it are imported from the Continent into Britain; and are various in appearance and quality, and obtained partly from the seeds of the winter rape, but more commonly from those of cole. The best kind, when new or pretty recent, has a yellowish-green colour, but becomes darker when long kept.

Every cargo or large quantity of rape-cakes, ought, immediately on its arrival, if the weather be dry, or as soon after as dry weather occurs, to be stored in a warehouse on a dry floor, either wooden or earthen, and built up in heaps clear of the walls, so as not to draw damp from them; and the place should be kept as free as possible from the admission of humid air, or even from

the admission of any kind of air. If the cakes be new, they will heat a little; and if they have not had a due 'sweat' in the ship, or may be apprehended to be more than usually prone to heat, the broken and pulverized portion of them should be separated and kept by itself. Both the dealer and the large consumer who keep a quantity of rape in the shape of dust by them, ought never to fling it down in the corner of a cart-shed, or in any similar place, where it is exposed to the humidity of the air, and to the interference of pigs and poultry. However dry it may appear, and however free from liquid moisture it may be kept, yet, on being laid somewhat thick together, it will sooner or later heat, and may eventually form a large portion of its substance into lumps as black as soot and not much different in internal appearance from coal cinders. Any heap of rape dust which threatens to become heated, should be spread as thin as the space for it will permit, and now and then turned carefully over.

A chief value of rape dust as a manure depends on its comparatively large proportion of nitrogen, and consists partly in the contribution which that element makes to the feeding of a crop, and partly in the readiness with which it sets up decomposition, and generates heat, and communicates the fermentative action to other dead organic substances which are more reluctant to decay. According to analyses by Boussingault and Payen, normal cole-cake contains 4·92 per cent. of nitrogen, while normal farm-yard manure contains only 0·4 per cent.; so that, in everything which depends on the action of nitrogen, 8·13 cwts. of cole-cake ought to manure as much land as 5 tons of farm-yard manure. But rape-cake also exerts very considerable manurial power, both by contributing earthy phosphates in direct nutrition to crops, and by combining the action of various saline and organic principles in the fermentative process within the soil. According to a testing process by Dr. Madden, 100 parts of rape-dust dried at 212° Fahrenheit give off 10·5 parts of water; and of the remainder, 24·7 are soluble in cold water, 4·8 are soluble in hot water, 31·5 are soluble in weak potash, 10·2 are soluble in strong potash, 14·3 are destroyed by heat, 3·0 consist of earthy phosphates, and 1·0 consists of silicate of potash.

Mr. Hannam, in his Prize Essay on Rape Dust and other Hand-Tillages, states, as practical conclusions from his own experience, that rape-dust produces its most marked effects on thin poor soils,—that it operates more beneficially in a dry season than in a moist one,—that it is most certain in its effects upon winter-sown wheat-crops, but, in favourable seasons, most remunerative on the spring crops,—that it answers best on strong soils for wheat-crops,—that it cannot judiciously be applied in large quantities at one time,—and that, when used for several rotations, it requires to be followed by a top-dressing of saline and earthy matters. Most practical writers, however, say that it does better on moist soils than on dry ones, and better on any land in wet seasons than in dry ones; and the truth may be that it does best in its proper or unmixed state on dry soils and in dry seasons, and best in a state of large dilution or controlling intermixture with other substances on moist soils and in wet seasons. Its valuable and powerful tendency to set up or accelerate decomposition in other substances requires that it be mixed with them, and is mightily aided by the presence of moisture; and this very tendency, at the same time, endangers the killing and rotting of the crop-seeds, if it be deposited in direct or undiluted contact with them, and may, in that case, be rendered mild and innocuous by the comparative absence of moisture. It also decomposes too rapidly, and becomes wastefully dissipated, when subjected unmixedly to the action of moisture; so that, whenever it is applied to moist land, or likely to be exposed to moist seasons, it should either be combined with some other and far bulkier organic manure, or largely diluted with an intermixture of ashes or of some dry porous earth. It may be used likewise to strengthen a liquid manure with an urine basis, to modify and enrich an excessively ammoniacal liquid manure, to form an artificial liquid manure by solution in water with the addition of some urine, and to set up decomposition with great speed and with highly fertilizing result in a compost of peat or of any other inert vegetable substance. In most modes of application, it is supposed to be destructive to the majority of insects which infest the soil; and, in mixture with elder or wormwood, in particular, it is thought to be an antidote against the wireworm.

Rape-cake is commonly reduced to powder in a one-horse mill at the rate of 5 tons a-day. The dust or powder is applied either in the drill, or in broadcast sowing, or in the way of top-dressing; and it is commonly given at the rate of from 10 to 15 cwt. per acre for turnips, and at from 10 to 12 cwt. or less for clover or grass or grain crops. When applied in the drill method to wheat, it does best to be partly given at the time of sowing in autumn, and partly drilled into the spaces between the rows in March and April,—for if given wholly in autumn, it is apt to make the plants grow too strong and root-fallen; and when applied in the broadcast method, it requires merely to be sown and harrowed in with the seed of grain crops, or to be sown on grass or on the braird of grain without harrowing. But when diffused over the surface as a top-dressing, a great portion of it is wastefully dissipated in gaseous products of decomposition, some is carried off by birds, and more or less is appropriated by weeds. Its proper use as a main ingredient in liquid manure is somewhat peculiar. "It is probable," says Mr. Rham, "that the most advantageous mode of using it on the land, after it has been dissolved in the urine

tank, is to apply it by means of a water-cart to the rows where the seed has been already drilled, or some time before it is put in. Where flax is to be sown, this mixture applied a few days before the seed is sown, so as to allow it to sink into the soil, is considered in Flanders as next in value to the emptyings of privies, which with them hold the first rank, for producing fine crops of flax. When a crop appears sickly and not growing as it should do, owing to poverty in the soil, a top-dressing of rape-cake, dissolved in water if no urine is at hand, will generally excite the powers of vegetation; and it is highly probable that it may greatly assist the effects of saltpetre or of nitrate of soda, where these salts are applied."

RAPHANUS. See Radish.

RAPHIOLEPIS. See Indian Hawthorn.

RAPISTRUM. A genus of yellow-flowered herbaceous plants, of the cruciferous order. It takes its name from the similarity of its leaves to those of the turnip. Two annual species and a perennial one, all hardy and less than two feet high, have been introduced to Britain from Continental Europe and the Levant; but they possess little interest.

RAPUNCULUS. See Bellflower and Rampions.

RASPBERRY. The *Rubus idæus* of Linnæus, belonging to the order *Rosaceæ* of Jussieu, is indigenous to the moist woods of many parts of Britain. The styles being persistent, the fruit has a bristly appearance, from which the name *raspis* or rasp has been given. The fruit is very desirable both for the dessert, and for making jam, tarts, and sauces. Eaten fresh with cream and sugar, it makes an excellent supper-dish, and may be had from July to November.

The varieties chiefly cultivated are the following: the common red and common white, the large red Antwerp, the large yellowish-white Antwerp, the cane or smooth-stalked, also called reed raspberry, the twice-bearing white, the twice-bearing red, and the Barnet or Cornwall's seedling,—"a variety," says Rogers, "which being raised from seed, will no doubt be the forerunner of a host of others." Some still prefer the common kinds of red and white, thinking that an increase of size in the larger varieties has been purchased at the expense of flavour; but the new varieties are, upon the whole, to be accounted preferable. The second crop of the twice-bearing kind is in general deficient both in flavour and size; but, by means of it, the raspberry season is prolonged till the beginning of November. It is to be particularly noticed, however, that the fruit should be regularly gathered as it ripens, and should be almost immediately used after being gathered; it will remain good on the bush for a few days after being ripe, but a dish of raspberries kept in the house for two days, will generally be found to have lost flavour, and to be tainted by maggots.

Sucker-shoots rising abundantly afford plenty of plants; but they should always be taken from stools in full bearing. They are planted any time from October to February. The distance is seldom less than three feet between the plants, and the quincunx order is generally adopted, five feet being left between the rows. If the larger varieties be planted, the distances are increased. A raspberry plantation continues good for six or seven years; but after the lapse of that period, it should be entirely renewed; it is generally in perfection the third year after planting; so that a new raspberry quarter should be prepared two years before the old one be grubbed up.

During summer raspberry-plants receive little attention. The ground is repeatedly hoed, and a few of the superfluous suckers are sometimes removed. Before winter, the ground is commonly dug and left rough. In some places the stools are dressed at this season (November); and a slight crop of coleworts is put between the rows. If this be not done, the general pruning is deferred till February or March, when the decayed stems of the former year are cut out, and the new ones regulated and tied: for there is this peculiarity about raspberry-bushes, that the stems which bear fruit in one year die in the following winter; leaving in their place a succession of new stems, which have been produced during the summer. Where the stools are very strong, six or eight stems are allowed to remain; but in young or weak plants, only half that number are suffered to carry fruit. At the same time, the tender tops which have been injured by frost and hang down, are cut off. Plants pruned or dressed before winter, it may be observed, sustain most injury from frost; the old stems, when left, affording a degree of protection to the young shoots. In exposed situations stakes are found necessary for supporting the stems; but in general it is thought sufficient to twist the shoots loosely together, and to tie them at top with a strand of bass-mat. Sometimes, the tips of half the shoots on one stool are tied to half the shoots of the next; and in this way a series of festoons or arches is formed, producing a very agreeable appearance, and at the same time affording security against the highest winds.

The raspberry-bush grows freely in any good garden soil; but it is the better for being slightly moist. Although the place be enclosed by trees, and even slightly shaded, the plant succeeds. In an enclosed and well sheltered quarter, with rather a damp soil, containing a proportion of peat-moss, we have seen very great crops of large and well-flavoured berries produced. Sometimes a few plants are trained against a west wall, or a trellis or rail, and the fruit here comes more early and of larger size. By training against a north wall, the crop is proportionally retarded. New varieties of raspberry are easily raised from the seed; and they come to bear in the second year.

RAT. The common brown or Norway rat, now so extensively diffused over this country, was almost, if not wholly, unknown in Europe until the year 1750. It was conveyed to England about the period above mentioned, in the timber-ships from Norway; and hence it has received one of its common names. Many years subsequently it was conveyed to America in European ships, and has been gradually propagated from the seaports over the greater part of that continent also. The brown rat takes up its residence about wharfs, store-houses, cellars, granaries, &c., and destroys the common black rat and mouse, or entirely expels them from the vicinities it frequents. To chickens, rabbits, young pigeons, ducks, and various other domestic animals, it is equally destructive, when urged by hunger and opportunity. Eggs are also a favourite article of food with this species, and are sought with great avidity; in fact, every thing that is edible falls a prey to their voracity, and can scarcely be secured from their persevering and audacious inroads. In the country, they take up their abodes according to convenience and the abundance of provision, infesting especially mills, barns, and out-houses, or residing in holes along the banks of races or other watercourses. The brown rat swims with great facility, and dives with vigour, remaining under water for a considerable time, and swimming thus to some distance. When attacked, and not allowed an opportunity of escaping, he becomes a dangerous antagonist, leaping at his enemy, and inflicting severe and dangerous wounds with his teeth. The most eager cat becomes immediately intimidated in the presence of one of these rats thus penned up, and is very willing to escape the dangers of an encounter. The brown rat is amazingly prolific, and, but for its numerous enemies, and its own rapacious disposition, would become an intolerable pest. Happily for the world, in addition to man, to the weazel, cat, some species of dog, &c., rats frequently find destructive enemies in each other, both in the adult and young state. The strongest of the species prey upon the weaker, and are the most merciless destroyers of their own kind. The weazel and the terrier are the most efficient rat-killers, as the first can pursue the enemy to his most secret retreat, and the second derives, from his superior strength and activity, a very decided advantage in the contest. The cat, though in general a very useful auxiliary in lessening the number of this species, is very liable both to be foiled and worsted in her attempts. As these rats bring forth from twelve to eighteen at a litter, we have good reason to rejoice that so many animals have an instinctive animosity against so noxious a marauder. The cunning of these rats is not less than their impudence; it is almost impossible to take them in traps, after one or two have been thus caught, as the rest avoid it with scrupulous care, however tempting may be the bait it contains. The surest way to remove them is by some special poison, or by means of peculiarly scenting the traps. See the articles Vermin and Mouse. The powder of *nux vomica*, mixed with oatmeal, and scented with oil of rhodium, is sometimes effectual in destroying them. Arsenic is commonly used in the same way for this purpose; but the fatal accidents which frequently occur when this poison is kept about the house, in consequence of the label being removed or changed, render it a very objectionable resource. The brown rat measures about nine inches, and is of a light brown colour, intermingled with ash and tawny. The colour of the throat and belly is of a dirty white, inclining to grey. It has pale, flesh-coloured, naked feet, with a tail of the same length as the body, and covered with small dusky scales, with short hairs thinly scattered between.—The *black rat* was much more common previous to the introduction of the brown rat than at present. It is now found only in situations to which the brown rat has not extended, and is almost as injurious and destructive, resembling it closely in manners and habits. It is of a deep iron-grey, and indeed nearly of a black colour above, and of an ash colour on the lower parts of its body. Its legs are nearly naked, and on its fore feet, instead of the rudimental thumb, it has a claw. The length, from the nose to the root of the tail, is seven inches; the tail itself is almost eight inches long. Blumenbach, who has devoted much attention to the subject, states it as his opinion that the black rat also was carried from Europe to America.

RATANHIA ROOT. See Krameria.

RATH-RIPE. The property of early ripening.

RATTAN. See Calamus.

RATTANY. See Krameria.

RATTLE (Red). See Lousewort.

RATTLE (Yellow),—botanically *Rhinanthus*. A genus of ornamental herbaceous plants, of the figwort family. Two annual species grow wild in Britain; two yellow-flowered, summer-blooming, hardy annual species, of respectively 12 and 20 inches in height, have been introduced from Continental Europe, and a number of other species are known. The name rhinanthus signifies snout-flower; and both it and the popular name yellow rattle, are descriptive,—the former alluding to the form of the corolla, and the latter to the rattling noise made by the capsules when handled.

The common or cock's comb yellow rattle, *Rhinanthus crista-galli*, abounds in poor meadows and pastures in many parts of Britain. Its root is fibrous; its stem is quadrangular, smooth, leafy, scantily branched, frequently spotted with red or purple, and commonly about a foot high; its leaves are lanceolate, acute, sharply serrated, spreading, rough, wrinkled, and from 1 to 1½ inch long; and its flowers grow crowdedly on a terminal, bracteated spike, and have a yellow co-

rolla and a smooth, ribbed, bladdery calyx, and bloom from June till August. This plant is far more a weed than a member of the grass lands which it inhabits; and it is disliked by cattle, both in the green state and in the state of hay.

The larger or bushy yellow rattle, *Rhinanthus major*, grows in corn fields in various parts of Britain, particularly in the north of England. It is annual, and has commonly a height of about 3 feet, and blooms in July and August; and it has more abundant branches than the preceding, narrower leaves, and smaller yellow flowers, with a purple upper lip.

RATTLER. See Aspen.

RATTLESNAKE ROOT. See Milkwort.

RAUWOLFIA. A genus of curious, tropical, evergreen, ligneous plants, of the dog's bane order. Three species with white flowers, and one with pink flowers, all propagable from cuttings, and varying in height from 3 to 14 feet, have been introduced to British collections; and 8 or 9 more are known.

RAVEN. The largest of the crow-family resident in Britain. Its body is of an ovate form, rather bulky; the neck strong, and of a moderate length; the head large and oblong; the bill rather long, deep, and nearly straight; the feet of moderate length and ordinary strength. The plumage is compact and highly glossed; the wings long and much rounded; as is the tail. The bill and feet are black; the plumage deep black, with splendent reflections of rich purplish-blue. The length of the male is twenty-six inches, and its extended wings measure fifty-two.

The raven is a remarkably grave and sedate bird, and is equally noted for sagacity and prudence. It is crafty, vigilant, and shy, so as to be with great difficulty approached, unless in the breeding season, when its affectionate concern for its young, in a great measure, overcomes its habitual dislike to the proximity of man; a dislike which is the result of prudence more than a mere timidity; for, under particular circumstances, it will not hesitate to make advances which a timorous bird would deem extremely hazardous. It eats from off the same carcass as a dog, and takes its station close to an otter devouring its prey, doubtless because its vigilance and activity suffice to enable it to elude their efforts to inflict injury upon it; and while it yields to the eagle, it drives away the hooded crow and the gull. It knows the distance, too, at which it is safe from a man armed with a gun, and allows the shepherd and his dogs to come much nearer than the sportsman. It never ventures to attack a man plundering its nest, and rarely pretends to be crippled, in order to draw him away from it, but stands at a distance, looking extremely dejected, or flies over and around him, uttering now and then a stifled croak indicative of anger and anxiety. When searching for food on the ground, it generally walks with a steady and measured pace; but under excitement, it occasionally leaps, using its wings at the same time, as when driven from carrion by a dog, or when escaping from its fellows with a fragment of flesh or intestine. Its flight is commonly steady and rather slow, and is performed by regularly timed beats of its extended wings; but it can urge its speed to a great degree of rapidity, so as to overtake an eagle, or even a hawk, when passing near its nest. In fine weather it often soars to a vast height, in the manner of the birds just mentioned, and floats, as it were, at ease, high over the mountain tops. Some naturalists having observed birds thus engaged, have imagined them to be searching for food, and have consequently amused their readers with marvellous accounts of the distances at which the eagle can spy its prey; but had they patiently watched, they might have found that the quiet soarings of the raven and the rapacious species have no reference to prey. On the other hand, it may sometimes be observed gliding along, and every now and then shifting its course, in the heaviest gales, when scarcely another bird can be seen abroad. Although there is not much reason for calling it "the tempest-loving raven," it would be a severe storm indeed that would keep it at home, when a carcass was in view.

In the Hebrides, where this bird is much more abundant than in any other part of Britain, it may be seen either singly or in pairs, searching for food, along the rocky shores, on the sandfords, the sides of the hills, the inland moors, and the mountain tops. It flies at a moderate height, proceeding rather slowly, deviating to either side, sailing at intervals, and seldom uttering any sound. When it has discovered a dead sheep, it alights on a stone, a peat bank, or other eminence, folds up its wings, looks around, and croaks. It then advances nearer, eyes its prey with attention, leaps upon it, and, in a half-crouching attitude, examines it. Finding matters as it wished, it croaks aloud, picks out an eye, devours part of the tongue, if that organ be protruded; and, lastly, attacks the abdomen. By this time another raven has usually come up. They perforate the skin, drag out and swallow portions of the intestines, and continue to feast until satiated or disturbed. In autumn it sometimes commits great havoc among barley, and in spring occasionally destroys young lambs. It has also been accused of killing diseased sheep by picking out their eyes. It annoys the housewives by sometimes flying off with young poultry, and especially by breaking and sucking, or rather gobbling eggs, which the ducks or hens may have deposited, as they frequently do, among the herbage.

The voice of the raven is a hoarse croak, resembling the syllables *crock*, *cruck*, or *chrro;* but it also emits a note not unlike the sound of a sudden gulp, or the syllable *cluck*, which it seems

to utter when in a sportive mood; for, although ordinarily grave, the raven sometimes indulges in a frolic, performing somersets and various evolutions in the air, much in the manner of the rook.

The character of this bird accords well with the desolate aspect of the rugged glens of the Hebridian moors. He and the eagle are the fit inhabitants of those grim rocks; the red grouse, the plover, and its page, of those brown and scarred heaths; the ptarmigan of those craggy and tempest-beaten summits. This species is also very abundant in the Orkney and Shetland islands. In Sutherland, Ross-shire, and many parts of the county of Inverness, it is also not uncommon. In most of the Highland districts we have met with it here and there. In the lower parts of the middle division of Scotland it is of much rarer occurrence; nor is it plentiful even in the higher and more central portions of the southern division, although we have seen it in many places there. In England it is much less frequently met with than in Scotland, although it seems to be generally distributed there also. If we take the whole range of the island as its residence, we must add to its bill of fare many articles not mentioned above, so as to include young hares and rabbits; other small quadrupeds, as rats, moles, and mice, young poultry, and the young of other birds, as pheasants, grouse, ducks, and geese; eggs of all kinds, echini, mollusca, fruit, barley, wheat, and oats; insects, crustacea, grubs, worms, and probably many other articles, besides fish and carrion of all sorts. In the northern parts of Scotland the raven constructs its nest on high cliffs, especially those on the sea-shore; but in the southern parts of the island, where rocks are not so common as tall trees, it is said frequently to nestle in the latter. According to the locality, it begins to repair its nest, or collect materials for forming a new one, as early as from the beginning to the end of February. In the maritime districts, it is generally composed of twigs of heath, dry seaweeds, grass, wool, and feathers. It is of irregular construction, and very bulky. The eggs are from four to seven, pale-green, with small spots and blotches of greenish-brown and grey, and are about two inches in length. The young are at first of a blackish colour scantily covered with soft, loose, greyish-black down. They are generally abroad by the middle of May. It has been remarked, that when, during incubation, or even when the young have left the nest, one of the old birds is killed, the survivor soon finds a mate. Ravens, if unmolested, breed in the same spot year after year.

Few birds are possessed of more estimable qualities than the raven. His constitution is such as to enable him to brave the fury of the most violent tempests, and to subsist amidst the most intense cold; he is strong enough to repel any bird of his own size, and his spirit is such as to induce him to attack even the eagle; his affection towards his mate and young is great, although not superior to that manifested by many other birds; in sagacity he is not excelled by any other species; and his power of vision is at least equal to that of most others, not excepting the birds of prey, for he is generally the first to discover a carcass. To man, however, he seems to be more injurious than useful, as he is accused of killing weakly sheep, sometimes destroys lambs, and frequently carries off the young and eggs of domestic poultry. For this reason he is generally proscribed, and in many districts a price is set upon his head; but his instinct and reason suffice to keep his race from materially diminishing. He seems to have fewer feathered enemies than most other birds, for although he may often be seen pursuing gulls, hawks, and eagles, we have never seen any species attacking him with the exception of the domestic cock. It has been alleged, however, that rooks assail him in defence of their young, and there is nothing incredible in this, for the weakest bird will often in such a case attack the most powerful and rapacious.

The species is very widely distributed over the globe, being more or less common in Europe, Asia, and America, but more abundant towards the arctic regions.

RAYGRASS. See RYEGRASS.

REAPING. The cutting down of ripe corn or pulse with a sickle, a scythe, or a reaping machine Most subjects connected with this operation are discussed in the articles SICKLE, SCYTHE, HAINAULT-SCYTHE, REAPING-MACHINE, BAGGING, MOWING, BANDS, SHEAVES, GAITING, RIDGE, HARVEST, FARM-SERVANTS, OAT, BARLEY, WHEAT, RYE, BEAN, PEA, and some others; so that the chief topics which fall to be noticed in the present article are ordinary reaping with the sickle, and the comparative merits of this practice and reaping with the scythe.

Reaping with the sickle, in so far as it is performed by specially hired reapers, is done by the season, or by the day, or by the acre, or by the bulk or amount of produce cut. In some districts or circumstances, each reaper cuts across the whole ridge, and makes bands and binds for himself; in others, a pair of reapers of unequal strength, often a man and a woman, have joint charge of a ridge, the stronger making bands for both himself and his fellow-labourer; in others, three or four or five reapers, of indiscriminate selection, or of nearly equal strength, have common charge of a ridge, each cutting along a narrow stripe of it, and all making bands and binding for themselves; in others, similar methods to the two preceding are practised, with the difference that one comparatively feeble worker, generally a female, makes bands and binds for every two reapers; and in others, one man and two women have joint charge of a ridge, the man cutting along the central portion and mak-

ing bands for both himself and the two women, and a binder or bandster following every two such sets of reapers and binding all the sheaves. The last of these is the method most common in the best districts of Scotland; and seems far the best for combining economy of strength or of labour with goodness of execution. Yet, says Martin Doyle, in decided preference of the next last, which is often practised in the cutting of wheat-crops in Ireland, "Two smart reapers with a fair crop will give a woman constant occupation in collecting and binding; and surely it is better at a critical season to employ the men in severing the corn alone, when active women can discharge the other part of the work equally well, and at a cheaper rate, too, and with the additional consideration that, by giving them such employment, the means of supporting their families are enlarged."

The art of reaping with the sickle, together with the risk of wounds on the part of beginners and the methods of dexterity on the part of the experienced, cannot be taught by book, yet may be promptly and easily taught by example, and need not therefore be described. But all reapers ought to have the habit of cutting the corn both evenly and low. Reapers who do not work in a sufficiently cowering posture, but keep their legs erect and bend the body only from the haunches, cut each sweep or breadth of the corn low in the front and high in the rear so as to give the surface of the stubble along a ridge the appearance of a series of notches; and the majority of reapers, whether they have this vice or not, and especially if they use the smooth and not the serrated sickle, are prone to cut so high from the ground as to leave a long stubble, and to cause a vast aggregate loss of straw. The desirableness of the shortest possible stubble, and the greatest possible quantity of straw, particularly in the vicinity of large towns where straw is sold at a high price, is the great motive for sometimes preferring the method of reaping called Bagging.

The comparative economy of reaping with the scythe, the smooth sickle, and the serrated sickle, has been much discussed, and is not well understood; and experiments for ascertaining it have not always, as they ought to have been, conducted under equally favourable circumstances, with implements of the most approved description, by scythemen and sicklemen equally dexterous in their respective art, and with sufficient scope and variety and frequency of repetition to detect and rectify contingent error. But a report on the subject, in the Highland Society's Transactions for July 1844, by Mr. John Taylor of Corsiestone, near Huntly, in Aberdeenshire, founded on "practical experience and minute observation," and prefaced with a full regard to the conditions of right experimenting, is so good that we cannot do better than give an abstract of it to our readers.

"In regard to binding," says Mr. Taylor, "the average number of sheaves, of an average crop of oats or barley, that one man can bind and stook in one day of ten hours, by these three modes, differs thus:—

Of sheaves reaped by the scythe, ...	1500
Of sheaves reaped by the smooth sickle, . . .	1200
Of sheaves reaped by the serrated sickle, . . .	1200

This difference is accounted for, first, by the mown sheaves being in regular rows of considerable length, the binder loses no time in moving from row to row, as in binding to shearers on two or three ridges; and, second, by mown stooks not requiring to be hooded. In practice, however, the binder binds less in a day to the scythe than to the sickle, because he binds to but one scythe, and the latter to six shearers, who reap more in a day than one scythe; but the binder to the scythe, if the crop be good, finds plenty of employment in assisting the gatherer in making bands. Sheaves reaped by the smooth and serrated sickles in the usual way are equally easily bound; but by the mode of reaping by the former, termed cuffing, the sheaves are not so neat, and the binder's work is more difficult, the sheaves requiring some dressing, and numerous fallen heads to be lifted up. Therefore, though a man may, and commonly does, bind as many sheaves in a given time, reaped by this, as by the usual mode, it must be by greater exertion, or else the work will be imperfectly done.

"In regard to winning, the prevalent opinion is, that grain reaped by the scythe is sooner ready for carrying than that reaped by either description of sickle, and my own experience is corroborative of this opinion. In regard to winning, the work of the smooth and serrated sickles, if done in the usual way, is quite the same. Sheaves reaped by the smooth sickle by cuffing (viz., striking with the sickle so as to cut and gather a sheaf together without grasping every cut with the left hand) have the advantage of being less compressed than if reaped in the usual way, but want the peculiarities of form which contribute to the winning of mown sheaves. In investigating the cause or causes of the difference of mowing and reaping, in regard to winning, the following peculiarities have particularly attracted my notice:—1, That, in a great majority of cases, and especially on narrow ridges, the straws composing a sheaf vary considerably in length. 2, That all the straws in sheaves, reaped by the sickle, reach to the bottom, or stubble end; and, therefore, including all the short straws within the sheaf, require the bands to be passed round near the bottom. 3, That binding in this way retards the process of winning in two ways—by compressing that part of the sheaf which most requires exposure, so as to render it almost impenetrable to the influence of sun and wind; and, by expanding its corn end so much, that when stooked, the stooks were almost as broad at top as at bottom; and, to defend these from rain, require hood-sheaves, which retard the winning of the grain. 4, That sheaves reaped by the scythe are even, or nearly so, at the top or corn end, and, to include all the short straws, require the bands passed round a little below the ears of corn. 5, That binding near the top expands the bottom, and gives the sheaf a tapering form from bottom to top; for though the straws are more numerous at top than at bottom, they are much smaller, more compressed, and consequently occupy less space. 6, That, when set up, the ridge of the stook is very acute, leaving the least possible admission for rain, and therefore requires no hoodsheaves. And 7, That, after heavy rain, stooks reaped by the scythe are sooner dry than those reaped by the sickle, because the wet naturally sinks toward the bottom of the sheaf, but the former, being open, allows it quickly to escape by evapora-

tion, while the latter, keeping it tight within the band, dries slowly.

"In regard to carrying and stalking, as has already been remarked, mown sheaves are closer and firmer at top than shorn ones, and, on this account, lose less grain by shedding than the latter, in the processes of carting and stacking. By observation, I am quite satisfied that this is the case, but cannot say precisely to what extent, nor could it be easily ascertained. Sheaves cut by the sickle are even at the stubble end, and, therefore, a stack wall is easier built of them than of mown sheaves, and has a more handsome appearance; but, being close, excludes the air from the interior. A stack wall of mown sheaves is rough but open, and can be put up with safety in a state of dampness, which would be destructive to shorn sheaves. When a crop is reaped with the scythe by inexperienced hands, a considerable quantity of grain is exposed on the outside of the stacks, owing to the straws having been irregularly laid into the sheaves; but with dexterous mowers, the quantity thus exposed will be very trifling, as it only happens when the wind blows in a direction contrary to that in which the crop has been laid by a previous storm, and not sufficiently strong to turn it completely back, that the mower finds it impossible to make an even swathe. A case of this kind rarely occurs, and when it does, the grain exposed in consequence need not be lost. A man with a scythe-blade fixed to a fork-shaft can dress a stack in an hour, spreading a sheet of canvass at the bottom to receive the heads of grain as they are cut off. With respect to carrying and stacking the work of the smooth and serrated sickles, provided they have been alike carefully performed, they are very little dissimilar.

"In regard to thrashing of mown and shorn grain, the flailman gives preference to the latter, because the grain is more exposed to the action of his implement, and is, therefore, more easily beaten out. In ordinary cases, a flailman can thrash about 10 per cent. more of shorn than of mown sheaves; and if the mowing has been improperly performed, the difference will be still greater. A good machine will thrash the one kind as effectually and expeditiously as the other; but mown sheaves are more difficult to part asunder than shorn, and although a man may feed both kinds equally fast into the machine, the former fatigue him more, as they require greater force to separate them. As to thrashing the work of the smooth and serrated sickles, it is much the same; however, by the smooth sickle, some straws are apt to be laid in a wrong direction, and usually some rakings are left, and a feeble or imperfect machine will not thrash the rakings and inverted straws perfectly—and, to thrash these well, they must be put twice through the machine. By the serrated sickle, fewer straws are in a wrong position, and there are no rakings to be dealt with.

"As to the amount of work performed by different modes of reaping,—having had many opportunities of ascertaining this point in various parts of Scotland, I shall here state what I have found to be the average amount of work performed by a band of reapers with scythes, and smooth and serrated sickles—the reapers being in every case thoroughly trained to their respective modes of reaping. Seven is the most convenient number, as six reapers require one binder, and two mowers require five attendants, viz., two gatherers, two binders, and one raker. Seven reapers, then, will reap of an average crop in one day of ten hours:—

	Of Wheat.			Of Oats or Barley.		
	Acres.	Roods.	Poles.	Acres.	Roods.	Poles.
By the scythe, . .	2	3	0	4	0	20
By the smooth sickle,	1	1	18	2	2	10
By the serrated sickle,	1	0	8	2	0	10

This shows a considerable difference in favour of the scythe, although I have stated the average extent of land reaped by expert shearers when working briskly. In this district, it is thought no great feat for one man to mow three acres of a light crop in one day; in fact, I have repeatedly done so myself, but with very great exertion; but of a fair crop two acres, or very little more, is as much as can be done; the mower might do more, but this is as much as two attendants can gather, bind, and stook, and a third cannot be employed to advantage.

"As to the comparative merits of the different modes of reaping, the preceding facts show a difference in favour of reaping by the scythe, with the exception of thrashing, which is comparatively an unimportant point, as the quantity of grain thrashed by the flail in Scotland is very trifling. There is another and somewhat serious objection urged by the opponents of mowing, namely, that more is left by it for the rake than by shearing, and that that so left is either lost altogether or deteriorates the rest of the crop if mixed amongst it. This, I admit, is, in many instances, true enough; but is it an unavoidable result of reaping by the scythe? Assuredly not. I beg to submit that I have employed mowers for ten harvests, and that the quantity left to the rake has not averaged more than 4½ per cent., which is little more than what is commonly left by the smooth sickle, and I have neither left the rakings to rot in the fields, nor spoiled the rest of the crop by them; and I know no good reason why others should do so. When a crop is reaped by the serrated sickle, there is nothing left to the rake, but this is its only recommendation; it is otherwise a laborious and expensive mode of reaping, and has now, with few exceptions, given place to the smooth sickle and the scythe. As it is now little in use, few can reap with it without uprooting part of the straw. With respect to learning to reap with the scythe and either kind of sickle there is this difference,—beginners with the sickle very soon learn to reap neat enough, but are defective in point of speed,—beginners with the scythe very soon learn to reap fast enough, but are defective in point of neatness. Both mowers and gatherers require some instruction, besides a few days' practice, before they can do their work properly; even although the former be good mowers of hay, they will require some practice in mowing grain, to enable them to lay it evenly in the swathe; but, if they are anxious to learn, a very short time will suffice;—and until mowers and gatherers are both expert, their conjoint work will appear rough and defective."

REAPING-HOOK. See Sickle.

REAPING-MACHINE. A machine for cutting down corn-crops and other field crops by means of horse labour. It is desirable for the sake of saving expense of reaping, of creating independence of temporary and precarious supplies of labourers, of expeditious harvesting in a fickle or critical season, of preventing over-ripeness in any part of suddenly and contemporaneously maturing crops, of commanding a competent harvesting apparatus for increasing breadths of corn cultivation in farms and districts, and of enabling farmers to thrash out a part of their crop immediately on its being carried from the field. Mr. Slight calculates, from the instance of the most recent good attempt at constructing an effective reaping-machine, that the expense of it, in the saving effected over the average cost of hand-reaping, would probably be saved

in one year; and he adds, "But suppose the price of a machine could be saved even in two years, the advantages would be very great, under the supposition that an effective machine could be procured for £30. It is deserving of consideration, also, that although no reaping-machine is to be expected capable of cutting down the crops in every possible state, yet we may infer that, even on a farm of ordinary extent, such a breadth of crop may be found, in almost any season, capable of being cut by a machine, as would save half the expense of the purchase. To obtain an effective and durable reaping-machine is, therefore, yet an important object to the farming interest."

This object, however, seems slow to be realized. Rude attempts toward it were made so long ago as the time of the ancient Romans; many and most ingenious attempts toward it have been made, both in Britain and on Continental Europe, in the course of the present century; several of the modern attempts have excited sanguine hopes, and have even seemed for a time to be entirely triumphant; and yet, for all purposes of general utility, a tolerably fair attempt, to say nothing of a really successful one, has yet to be made. The very best of the many reaping-machines hitherto constructed, though very beautiful and highly ingenious pieces of machinery, are but a degree better than mere curiosities, and do not require therefore to be lengthily described. Three of them, indeed—Smith's, Bell's, and Mann's—do pretty well on crops which everywhere stand quite erect, or which, if inclined at all, are inclined but slightly and everywhere in one direction; but all fail, or make most unsatisfactory work, on crops which are contorted by winds or lodged by rains.

Boyce's reaping-machine was patented early in the present century, and was the first reaping-machine of considerable promise. It was mounted on a two-wheel carriage, somewhat similar to a common cart, but with fixed wheels or revolving axle; it had a vertical spindle which descended to the proper cutting distances from the surface of the ground, and was there armed with a number of horizontally adjusted scythes; it communicated motion to the spindle by mechanical connexion with the revolving axle of the carriage; and it hence cut down the growing corn by a rapid revolution of its scythes,—a revolution produced by the carriage being wheeled along; but it had no provision for gathering the corn into parcels or for depositing it in heaps or in any proper order.

Plucknet's reaping-machine, made by an agricultural implement maker of that name in London, was similar in general structure to Boyce's, but, instead of the scythes, had a notched, sharp-edged, circular steel-plate, which cut the crop with a similar action to that of a very fine toothed saw.

Gladstone's reaping-machine, made by Gladstone of Castle-Douglas in Kirkcudbrightshire, was even nearer in principle to Plucknet's than Plucknet's was to Boyce's; but it consisted of superior workmanship, and comprised contrivances for keeping the cutting edge in constant sharpness, and for gathering the cut corn and depositing it in parcels.

Salmon's reaping-machine was made by Salmon of Woburn, and was a still later invention than Gladstone's, and was constructed on a widely different principle, and gave still higher promise of success. It cut the corn by means of shears, and had an ample and effective apparatus for depositing it in parcels.

Ogle's reaping-machine was invented in 1822 by Mr. Henry Ogle, schoolmaster at Rennington, near Alnwick, in Northumberland, and was undertaken to be furnished by Messrs. Brown, iron-founders in Alnwick, and comprised apparatus for sheaving corn as well as for cutting it, and was estimated to cut 14 acres per day, and is said to have done its work on trial in a satisfactory way, yet does not seem to have ever won the confidence of any practical farmer. A figure and a description of it may be seen in the 5th volume of the Mechanic's Magazine.

Smith's reaping-machine, the invention of Mr. Smith of Deanston, was tried so early as 1811, and came prominently into notice in 1816, and underwent a series of important improvements from the period of its first trial till about the year 1837. It from time to time excited great hopes; and seemed at each successive improvement to have almost reached the point of complete success; yet, it is probably farther at the present day, than ever it was, from coming into ordinary practical use. Its cutter is a continuous circular knife, revolving with considerable velocity; and its gathering apparatus comprises a revolving rake, placed over and concentric with the cutter, and lays the cut corn down at one side of the track of the machine. It is pushed by two horses, and cuts a breadth of about 4 feet; but it has a length of about 20 feet, and is exceedingly unwieldy.

Bell's reaping-machine, invented by the Rev. Patrick Bell of Carmylie in Forfarshire, was put into operation in 1827, and received a premium of £50 from the Highland and Agricultural Society of Scotland; and during several years, it was much talked of among the best-informed circles of agriculturists, and seemed to bid fair to render itself worthy of practical adoption; yet, almost or quite as much as Smith's, it has caused eventual disappointment, and is passing into oblivion. It cuts on the clipping principle, by means of a series of shears; and it combines with this a gathering apparatus which lays the cut corn on an endless web, and, by means of this, deposits it along one side of the machine's tract. It is pushed by two horses, and cuts a breadth of 5 feet. A figure and description of it may be seen in the first volume of the Quarterly Journal of Agriculture.

BELL'S REAPING MACHINE.

Mann's reaping-machine, invented by Mr. Joseph Mann of Raby, near Wigton, in Cumberland, was first of all tried in 1822, and first tried in an improved form in 1826, and first tried in Scotland at the Kelso meeting of the Highland Society in 1832. It made similar promise to Smith's and Bell's; and had it been as perseveringly improved as the former, it might possibly have won the confidence of practical men; but—quite as much perhaps from want of hope on the part of its proprietor, as from want of encouragement on the part of leading and influential agriculturists—it is going to rust along with its predecessors. It has a revolving polygonal cutter of 12 equal sides, and produces its cutting effect by a very rapid series of strokes; it gathers the cut corn by means of revolving rakes, and strips these in such a manner as to lay down the corn in a regular swathe; it is drawn by one horse walking along the side of the standing corn; and it cuts a breadth of 3½ feet at each turn, and is capable of cutting about 10 acres in 10 hours. A figure and a description of it may be seen in the 6th volume of the Quarterly Journal of Agriculture.

REARING. A horse's tossing aloft his two fore legs, so as momentarily to poise his whole body on his two hinder feet. This proceeds sometimes from playfulness, sometimes from sharp reining, and sometimes from sheer vice; and in the first and second cases, it may be cured by using a snaffle-bridle,—but, in the third, is both incurable and very dangerous. A viciously rearing horse, indeed, is sometimes dealt with by being pulled over backward by a rider upon a soft piece of ground; but this risks both the spine of the horse and the neck of the rider,—and implies an appalling degree of both brutality and recklessness.

REDBREAST,—*Motacilla rubecula.* A bird familiarly known to every child, from the numerous stories in which it plays a prominent part. The fame of this bird has arisen from its habit of seeking the aid of man during the winter season. During that inclement period of the year, it visits without dread the cottage of the peasant and the palace of the peer, tapping at the windows with its bill, as if to demand an asylum, and repays its host by its confidence, gathering the crumbs from the table, and warbling forth its thanks in the softest notes. The moment, however, the spring appears, this familiarity with its protectors ceases, and it again hastens to its native haunts. The redbreast builds its nest at the foot of some shrub or upon a tuft of grass; it is composed of dried leaves, mixed with hair and moss, and lined with feathers; the female lays from five to seven eggs. Sometimes it covers its nest with leaves, leaving a small passage for egress and regress. The food of the redbreast varies with the season; in the spring it is composed of worms and insects, but in autumn is principally fruits and seeds. Its delicacy in preparing a worm before partaking of it, is somewhat remarkable; it first seizes it by one end in its beak, and beats it on the ground till the inner part comes away; then, taking it in the same manner by the other end, it cleanses the outer part, which is the only portion it eats. From its general familiarity with mankind, it has received a *nom de caresse* in almost every nation in Europe; in England it is known as the *Robin Redbreast;* in Germany it is termed *Thomas Gierdet;* and in Norway, *Peter Ronsmad.*

REDBUD. See Judas Tree.

RED CEDAR. See Juniper.

RED CLOVER. See Clover.

RED-CRAIG. See Marl.

RED GUM. See Rust and Mildew.

RED LAND. See Soil.

RED LEAD. The sesqui-oxide of lead, or a mixture of the protoxide and deutoxide. It is well known in commerce, as a pigment, and in the manufacture of flint-glass. See the article Lead.

RED PINE. See Pine.

REDPOLE. Two British song-birds, of the linnet genus and finch family of passerinæ.—The smaller or common redpole, *Linota linaria,* is the smallest of the British linnets; and has a total length of 4¼ inches. The upper part of the body is brown, spotted with black; the wing is traversed by two white bands; its throat is black; the breast and the top of the head of the adult male are red; and the rump also is sometimes red. This bird resides throughout the year in Scotland and the north of England; and appears in small flocks from Michaelmas till April in the south of England. It feeds on the buds of trees, and on willow, birch, and alder catkins; and, when it lives in flocks, it sometimes inflicts severe injury on plantations. Its nest is built in a bush or low tree, and consists of moss and dried grass and willow catkin down. Its eggs amount to 4 or 5, and have a pale bluish green colour, spotted with orange brown.—The larger or mealy or stone redpole, *Linota canescens,* is regarded by some naturalists as only a larger variety of the common species. It is about 5¼ inches long; and it differs from the common redpole, both in the size of the bill and in some tints of the plumage.

RED-RAG. See Rust and Mildew.

RED RATTLE. See Rattle.

RED ROBIN. See Rust and Mildew.

RED SANDSTONE. See Geology.

RED SAUNDERS WOOD. See Pterocarpus.

REDSHANK,—scientifically *Totanus.* A genus of birds, of the grallæ order. Their form is light; their legs are long; only a small part of their thumb rests on the ground; their external web is well-marked; their bill is slender, solid, round, and pointed; their nasal fossæ do not extend through more than one half of their bill; and their upper mandible is slightly arcuated near the end. The several species occur through-

out the greater part of the world; and two of them frequent the shores of Britain.

The common redshank, *Totanus calidris*, inhabits many parts of Britain throughout the year, but frequents the coast in flocks during winter, and the fens and marshes adjacent to lakes and streams singly or in pairs during spring. It feeds on aquatic insects and worms, and probes for them in mud and silt. Its extreme length is about 11 inches; but is greater in the female than in the male. In winter, the upper part of its body is ashy brown, and the breast, the belly, the front of the neck, and the stump and tail feathers are white, with a few slight dusky streaks in the line of the shaft of the feathers; and in spring, the under part of the body, the sides, the flanks, and the front of the neck are streaked and spotted with brownish black. It builds its nest with coarse grass in the fens, and begins to lay early in May; and its eggs have a pale reddish white colour, tinged with green, and blotched with dark red brown.

The spotted redshank, *Totanus fuscus*, is a great deal rarer than the common species, yet is sent not unplentifully to the London market in autumn and winter. Its total length is about 12½ inches. Its bill is straight and moderately long; its plumage is ashy on the back, grey on the breast, and pure white on the belly at one season, but changes to a sooty black at another; and its legs and toes have a vermillion red colour, and its wings white spots, throughout the year.

RED SPIDER,—scientifically *Acarus Telarius*. A plant-infesting mite,—a minute microscopic animal, of the holetra family of spiders. It belongs to a prodigiously multitudinous genus, which infest a large proportion of the organic tribes of our world, in both their living and their dead states, and many of which are parasites, and have an intimate connexion with some of the most loathsome cutaneous diseases of mammals. All the acari or mites are oviparous and amazingly prolific.

The red spider or common plant mite is a great and general destroyer among the tender and half-tender exotics of the garden, and vies with the aphides in giving work and vexation to gardeners, and, not only has a prodigious fecundity, but multiplies almost equally at all seasons of the year. The eggs are generally deposited on the back of leaves, where they are best sheltered from strong light; and they are very minute, and of a whitish colour, and not collected in masses, but scattered loosely and dispersedly all over the surface. The young ones, soon after being hatched, begin to move about upon the leaves. They are at first colourless, and remarkably small, but of the same form as the parents; and as they advance in growth, they become more and more red; and when they are half-grown, they become very active; and when they attain maturity, they are dark brown and slightly hairy. During the progress of their growth, they several times cast their skins; but they do not undergo any other apparent change except increase of size and darkening of colour. They weave for themselves close silken webs; and they travel by means of these from one leaf to another; and the young are also sheltered by them from the sickening or killing effects of ordinary moisture. Both the middle-aged and the full-grown animals are so very minute, that, except when viewed through a microscope, they appear on the leaves like mere red moving dots.

Many means have been proposed of destroying the red spider or of preventing its appearance. One of the simplest and most efficacious, at any season of the year or in any condition of the plant-house in which it can be applied without injury to the plants, is excessive humidity; and a kindred one, which can often be applied at other seasons and other conditions, is daily syringing with clear water. Another is to bruise laurel leaves beneath the infested plants, so as to kill the spider with their liberated, aeriform, essential oil; but this amounts to the diffusion of prussic acid through the local atmosphere, and is dangerous to man. Most of the other remedies derive their efficacy from sulphur, applied in many forms and in many combinations, either aeriformly or liquidly or as a wash upon flues or walls; and one of the oldest-fashioned or most extensively employed of these may be selected as a good enough coarse specimen of all the rest:—"Take half a pound of flower of sulphur; put it into a watering pot, and add as much water as will make it into a paste; afterwards add more, until sufficiently thin; pour it into a garden engine or other vessel capable of holding 4 or 5 gallons; then add as much water as will make it into 4 gallons; and water the infested plants with this overhead, and repeat the application till every insect disappears."

Two facts respecting the red spider are remarkable,—that it is thought by some intelligent observers to be rather useful than injurious to plants, and that another and certainly harmless species of acarus is often mistaken for it. The way in which it is supposed to be useful is by its destroying the *Coccus hesperidum* or brown scale, and sometimes also different species of aphides; and the acarus which is mistaken for it is *A. holosericeus*, or the scarlet spider, which is much larger than the red spider, and lives solitarily, and does not form any web, or fix on any particular plant or leaf for its residence.

REDSTART. Two British song-birds, of the warbler family of passerinæ.

The common redstart, *Phœnicurus niticulla*, *Sylvia phœnicurus*, or *Motacilla phœnicurus*, arrives in the southern counties of England about the second week of April, and proceeds thence toward the west and the north. It is rare in some places, and not very plentiful in any. Its total length is 5¼ inches. The head, back, and

wing-coverts of the male are leaden grey; the forehead is white; the chin, the throat, and the side of the face and neck are jet black; the breast and the belly are pale chestnut; and the legs and the toes are brown. This bird inhabits gardens, orchards, parks, meadows, and the skirts of forests; and builds on ruins, old walls, decayed trees, and many very curious situations; and feeds on worms, beetles, flies, ants, larvæ, spiders, and various kinds of garden and orchard fruit. Its song is soft, and has something of the modulations of the nightingale. Its nest is loosely built, and consists externally of moss, and internally of hair and feathers. Its eggs amount to from four to eight, and have an uniform greenish blue colour.

The black redstart is variously called, as to genus, *Phœnicurus*, *Sylvia*, and *Motacilla*, and, as to species, *tithys*, *tytys*, *erithacus*, *atrata*, and *gibraltariensis*. It is much more uncommon than the common redstart, and may be readily distinguished from it by the sooty colour of its breast and belly. Its total length is $5\frac{3}{4}$ inches. The bill of the male is black; the irides are blackish brown; the back, the neck, and the top of the head are dark bluish grey; the wing-coverts are greyish black; the rump and the tail-coverts are chestnut; the cheeks, the throat, the breast, and the sides are sooty grey; the belly is slaty grey; and the legs and toes and claws are black. This bird has similar habits to the common redstart, but delights in stony places, and is seldom seen in low and level districts. It feeds on worms, larvæ, insects, garden berries, and the smaller garden and orchard fruits; and builds in walls, roofs, clefts of rocks and similar situations. The nest consists principally of grass, with a lining of hair; and the eggs amount to 5 or 6, and are white, smooth, and shining.

RED WATER. A common, severe, and untractable disease in cattle and sheep.

Red water in cattle is also called hæmaturia, moor-ill, darn, bloody urine, foul water, and, in its last stage, black water. It has been the subject of much discussion, both in Britain and on the Continent, both among practical observers and scientific men; and it continues, in a considerable degree, to be the topic of diversified and conflicting opinion as to at once its causes, its nature, and its proper treatment. Seven select essays on it may be seen in the 9th volume of the Highland Society's Transactions; and discussions of it, more or less valuable, occur in the Veterinarian and in all the best treatises on veterinary medicine.

Red water is sometimes acute and sometimes chronic, sometimes isolated and sometimes epizootic, sometimes apparently connected with particular kinds or states of pasture and sometimes apparently unconnected with any particular kind of pasture, generally irrespective of any distinctions of breed or sex or age or condition of cattle, and occasionally peculiar to cows immediately after parturition; and it may, therefore, be in some sense regarded, not as strictly one disease, but as a group of mutually related or mutually similar diseases.

When it attacks newly calved cows, it probably arises from change of food about the period of parturition, or from want of sufficient cleansing, or from previous fulness of the blood, or from all these causes or any two of them combined; when it attacks cattle on particular pastures, and does not attack cattle on immediately adjacent ones, it probably arises, wholly or partly, from the eating of acrid plants, such as *Ranunculus acris*, *Ranunculus flammula*, *Anemone nemorosa*, and *Anemone ranunculoides;* but when it makes its attacks in other circumstances, or does not appear to have any traceable connexion with peculiar states of herbage, it probably arises from such a complication of causes as cannot be easily or very certainly explored. Mr. Robert Thomson, the first of the Highland Society's essayists, says, "It is most prevalent in old foggy pastures. It is seldom seen in hill pastures, or in new sown pastures, in which there is abundance of clover; but it sometimes happens at the stall, where the animal has no other allowance than straw, turnips, and potatoes. It usually makes its appearance after a few days of rain, followed by cold dry weather." Mr. William Laing, another of the essayists, says, "I am led to infer that close confinement in winter is one predominating cause, the cattle being thus deprived of the necessary exercise, fresh air, and access to earth, which seems to be useful in correcting the acidity produced in the stomach by costiveness and obstructed bile. Frosty water is also another cause, as it tends to produce indigestion, bad chyle, and consequently bad blood. Barley chaff, given in its natural state, but more particularly when boiled, may also occasion it, by destroying the sensibility of the villous coats of the stomach. It occurs most frequently in the end of autumn, in winter, and more particularly in the early part of spring." Mr. A. Watt, a third of the essayists, says, "It is produced by dry food, difficult of digestion, and is always found among cattle that are fed off newly improved lands, and on turnips and straw that have grown on poor ground. Neglect of proper watering, and feeding on turnips after they have begun to grow in spring, are also causes." And Mr. Andrew Henderson, a fourth of the essayists, states, as the result of extensive observation during 20 years, that "upon a light soil, liable to be soon burnt up for want of moisture, he found ten attacks of the disease for one upon any of the neighbouring farms which might happen to have a deeper soil," — that "the prevalence of the disease in such a situation was solely regulated by the state of the season, for in a moist season not a single instance perhaps would occur, while in a dry one numerous cases would appear,"— that, while passing by stock who were stationary

it occasionally attacked cattle who experienced a change of pasture, particularly when the change was from fine to coarse herbage,—and that, in the course of most journeys of droves of cattle from Scotland to the markets of the south of England, many violent attacks occurred; and in reference to the last of these facts, he says, "I have observed, that 20 females for one male were attacked, and more especially such as had had calves,—that at the commencement of the journey, the disease was not prevalent, provided there was a constant supply of water, and the weather proved steady,—that during a long-continued drought, the cattle were very subject to the disease, especially when pure water could not be had,—that sudden changes of weather were also apt to induce the disease,—and that at the commencement of the journey, some of the cattle were generally affected, although no perceptible change had taken place in the quality of the food, and although the cattle had not been exposed to any of the above causes. This must have proceeded from inflammation induced by sprains, bruises, or over-heating, caused by the cattle fretting and riding upon each other, as well as by the unmerciful strokes of the drivers." These details of observed causes in the course respectively of calving, of depasturing, of farm-yard feeding, and of journeying, ought to suggest to all proprietors of cattle-stock the several and most effective means of prevention.

"The first symptom of red water," says Mr. Thomson, "is the appearance of something like blood mixed with the urine. So trifling is the complaint in some instances, that no inconvenience seems to be felt by the animal, which eats and drinks as usual, chews the cud, and is free of the disease in a few days. In such cases, a natural diarrhœa comes on, to which the cure may be attributed. In general, however, the disease is not observed until the animal refuses food, separates from the rest of the herd, appears dull and heavy, and manifests great languor and apathy. The ears droop, the urine is of a reddish or brownish colour, and if it be a milch cow, the milk is often similarly tinged. The pulse ranges from 60 to 70; there is obstinate constipation of the bowels; the urine is discharged in moderate quantity, and apparently without pain. If relief is not afforded by some brisk purgative, at the period when the urine changes colour from red to brown, the pulse begins to sink; and if a little blood be drawn at this time, its surface assumes a brownish colour; the eye appears of a yellowish brown tint; the urine acquires a darker hue; the animal refuses to rise; the pulse sinks; the legs, tail, and horns, turn cold; and the animal dies, to all appearance perfectly exhausted, although it has manifested no symptoms of acute pain during the course of the disease. On removing the skin in animals which have died of this disease, the subjacent parts have a peculiar dark yellow appearance. The abdominal fat has the same colour. The first and second stomach are generally pretty full of food. The third stomach, or manyplies, is dry; its rugæ are inflamed; its contents compressed as by general spasm. The fourth, or true stomach, is nearly empty; its gastric juice tinged of a dark yellow colour. The small intestines show no marks of inflammation, but their mucous coat is tinged of the same colour. The rectum contains indurated fæces covered by brownish slime. The liver is of a darker colour than natural, but does not appear to be diseased in structure. The gall-bladder, in all cases that I have seen, is full of black, thick bile, somewhat resembling lamp-black and oil. The ductus communis choledochus does not appear to be obstructed, or if it is, this is effected by the presence of the neighbouring viscera. The fat surrounding the kidneys is healthy, but of a dark yellow tint. The kidney shows no appearance of disease, and, on being compressed, emits a few drops of urine similar to that in the bladder. The latter organ is healthy, but full of dark-coloured urine, resembling the thinner parts of the contents of the gall-bladder. There is no accumulation of fluid in the cavity of the peritonæum. The thoracic viscera are healthy, but tinged with yellow, as are the liquor pericardii, and the cerebral fluid. The contents of the lacteals and thoracic duct are of a dark brown colour. From the above appearances, the third stomach might seem diseased, but if water or liquid drinks be given plentifully before death, this appearance of dryness of the contents and inflammation will not take place. We must, therefore, seek the cause elsewhere. The kidneys are healthy, but the urine is tinged brown. The whole secretions are also more or less tinged. Shall we suppose, then, that the whole apparatus of secretion is diseased, or that the absorption of black inspissated bile into the blood colours all the secretions, as jaundice does in the human subject? This seems the most reasonable supposition. Bile regurgitated into the substance of the liver, can be taken up by the absorbents and passed into the blood, causing derangement of the functions of secretion, and giving a red appearance to the urine, milk, &c. If constipation of the bowels be present, the bile may be taken up by the absorbents of the mesentery, and introduced into the circulation; and, if continued for some time, the whole blood will become poisoned as it were, and unfit for the support of animal life, although there is no appearance of mortification in any part of the system, but all the secretions, together with the fat, are more or less tinged with a dark brown or yellow colour."

The empirical treatment of red water, on the part of stock-farmers, cow-doctors, and veterinary quacks, exhibits the most astonishing variety, and comprises almost a museum of absurdity, and might be instructively detailed, through scores of grotesque and monstrous particulars.

in illustration of human ignorance and folly. Even the professional treatment of it on the Continent has a strong dash of the vague and the ridiculous. But the treatment recommended by all the best British veterinarians is intelligible and simple, and consists mainly in purgation, accompanied with the administration of subordinate remedies suited to the secondary or adventitious symptoms. Mr. Thomson's prescription is one of the clearest, and is declared by Youatt to "comprise the substance of that treatment which is founded on principle, and will be attended by success where success can be attained," and is stated in the following terms:—"Purgatives of any kind, if given in large quantities of water, are found to be the best medicines that can be employed. Medicines given to cattle that have lost the power of chewing the cud, generally pass into the first and second stomachs, and if a good draught of water is not given to wash them from thence, if the animal dies the greater part of the medicines will be found in these stomachs; and upon this principle, common salt, if properly managed, will be found among the best. Dissolve the quantity to be given in as much water as will enable it to pass freely from the bottle or drenching horn, and let the animal have plenty of water to drink afterwards. Should it refuse to drink, no time should be lost in drenching it profusely with water. Without a plentiful dilution, there is no certainty of purging cattle that have lost their cud. If purging does not commence in from 12 to 24 hours, a second dose should be given. Injections of soap and water should also be tried if the case is obstinate, and when they operate, a pint of linseed oil should be given as a laxative. So obstinate is the constipation in some cases, that the salt acts only as a diuretic, causing a plentiful discharge of urine. Diuretics and astringents combined seem only of service when the bowels are open, and their improper administration often causes inflammation of the bowels and kidneys. If, after purgation, the bowels are kept open by laxatives, such as linseed infusion, the disease will gradually disappear without their use. In the last stage of the disease, when the urine assumes a dark-brown or black colour, no remedy seems to have any efficacy, the animal is sunk beyond recovery, the bowels lose their action, suppression of urine follows, the animal stretches itself out and dies, as if perfectly exhausted. It is the duty of the owner, then, to attend to the disease at its commencement, and pursue a determined course of practice. Whether the disorder be owing to absorbed inspissated bile, diseased manyplies, or disease of the secerning glands, purgatives of any kind, profusely diluted with water, almost always effect a cure." Some good practitioners, especially when constipation and excitement have occurred before they can prescribe, begin with letting blood, and purge with a mixture of Epsom salt, flowers of sulphur, powdered ginger, and carbonate of ammonia, and, after purgation is fairly established, administer mild stimulants or nourishing drinks.

Red water, both in cattle and in sheep, is often popularly confounded, both in name and in symptom, with inflammation of the kidneys and inflammation of the urethra or of the mucous membrane of the bladder. The urine discharged in these diseases is mixed with blood, but not so intimately as in redwater, and generally with more or less accompaniment of mucus. Inflammation of the bladder or of the kidneys may easily be distinguished by this difference in the bloodiness of the urine; and, like every other case of acute inward inflammation, must be attacked with copious bleeding and with purging, yet must either not at all or very cautiously be assailed with counter-irritation. See the article Inflammation.

Red water in sheep is less precisely understood, as to either cause or nature, than red water in cattle; and it sometimes bears the name of resp, and sometimes that of water braxy. "Some persons," says Mr. Cleeve, in his Prize Essay on the Diseases of Sheep, "treat this complaint as inflammation of the kidney. It is extremely probable that, in all cases of red water, the inflammation of the abdomen may extend to the region of the kidney, and thus some of the indications that appear may lead the observer to suppose that the kidney is the primary part affected; but my opinion, founded upon post-mortem examination of the subject, is, that the inflammatory action has its origin in the peritoneum, and, consequently, that change of diet and attention to the bowels are the first points to which the care of the shepherd should be directed. If this opinion is well founded, diuretic medicines are not judicious. Feeding on turnips when covered with hoar-frost is supposed to occasion the complaint. Another, yet more probable, cause may be folding sheep on wet soil during frosty nights. The progress of this disease, as indeed is the case with all acute inflammation, is very rapid; so rapid as to occasion death in most instances before the existence of it is suspected. Where its progress allows of observation, the indications of it are costiveness of the bowels and great pain and distress; the animal appearing incapable either of rest or active motion from the violence of its sufferings. Its name is derived from an accumulation of bloody fluid in the abdomen. The remedy is, as I have already mentioned, copious bleeding, even until fainting takes place, and this followed by opening medicine: but it is so rarely the case that a cure can be expected, that, if the sure symptoms of it are perceived, the best way is to kill the sheep before they have obtained their height. Where I have succeeded in removing the inflammatory symptoms, I have immediately changed the food, and put the sheep on bran and oats, very liberally sprinkled with salt. I also

provide water very copiously. Red water has sometimes been called 'Watery Braxy,' but I apprehend that the braxy is more properly a retention of urine, proceeding from inflammation of the bladder, as the dry braxy is another name often applied to inflammation of the bowels. I never met with a case where a ewe laboured under retention of urine. When it occurs it most frequently attacks rams, and many valuable sheep have been lost from its effects. I have remarked it to have been generated by placing them on clover that had previously been mown. As it may be easily detected by the distension and tenderness of that part of the body externally, the water can be successfully drawn off by a catheter. It may not be unnecessary to caution the shepherd that diuretic medicines are most injurious in a retention of urine, as they increase the secretion of the fluid without in any way facilitating the discharge." See the article BRAXY.

RED-WING, or MAVIS,—scientifically *Turdus Gliacus*. A British song bird, of the thrush genus, and passerinous order. It arrives from the north and north-east of Continental Europe in the latter part of October, and remains in Britain through the winter. Its total length is about $8\frac{3}{4}$ inches. The upper part of the head and neck, the back, the rump, and the upper tail-coverts are uniform clove brown; the chin, the throat, the belly, and the under tail-coverts are dull white, tinged and streaked with brown; and the sides of the body, the under wing-coverts, and the axillary feathers are bright reddish orange. This bird inhabits wooded pleasure-grounds; and passes in mild weather into pastures and meadows; and feeds on worms, larvæ, and slugs.

RED WOOD. See CEANOTHUS.

REED. See ARUNDO.

REED-GRASS. See CANARY-GRASS.

REEL. The instrument on which a gardener's lines are wound; also, the instrument attached to the butt of an angling-rod for winding in the fishing-line.

REGULUS. A genus of song-birds of the warbler family and passerinous order. The kinglet or golden crested regulus, *R. amicapillus*, is one of the smallest of British birds, and remains in this country throughout the year. Its total length is about $3\frac{1}{2}$ inches. The forehead is greyish white; the crest feathers are bright yellow, tipped with orange; the back and the upper tail-coverts are olive green, slightly tinged with yellow; and the wing and the tail feathers are brownish black, edged with greenish yellow. This bird most commonly frequents fir plantations, and builds on the branches or twigs of the fir-tree; and it feeds on insects, seeds, and small berries. The eggs amount to from 6 to 10, and have a pale reddish white colour.

The fire-crested regulus, *R. ignicapillus*, is not so common as the preceding species, and is about half an inch longer, and has three dark lines and two light ones on the side of the head, while the golden-crested regulus has only one black line. Its crest also is of a much more vivid red colour; and its tail feathers are longer.

REIN-DEER. See DEER.

REINS. See BEARING-REIN and BRIDLE.

RELHANIA. A genus of ornamental, small, evergreen, Cape-of-Good-Hope undershrubs, of the sunflower division of the composite order. Five or six species, all yellow-flowered, and loving a soil of peaty loam, and propagable from cuttings, and varying in height from 6 to 24 inches, have been introduced to British gardens; and upwards of a dozen more are known.

RENANTHERA. A genus of ornamenal, tropical, epiphytous plants, of the orchis order. The scarlet species, *R. coccinea*, is a native of China, and was introduced to Britain in 1816. It was long known to fame as one of the most magnificent flowering plants in the world, and is now celebrated as one of the most splendid beauties of our most select stove collections; but it requires peculiar and nice treatment in order to be brought to bloom. It has long fleshy tortuous roots, and long leafy stems, and veinless fleshy leaves, and vast panicles of scarlet flowers; and it commonly attains a height of about 8 feet, and blooms from March till May, but may be so managed as to be kept in high and even perfect flourish during about four months. It succeeds best in peat mixed with reduced potsherds, and requires a high play of combined heat and moisture; and when 6 or 7 feet high, it must be placed in full exposure to the sun's direct rays, and occasionally washed over in the afternoon with a syringe. It is propagated from shoots or young branches, taken off and potted in moss. The name renanthera alludes to the kidney-like shape of the pollen masses.

RENCALMIA. A genus of ornamental, white-flowered, evergreen, herbaceous, greenhouse plants, of the iris order. Three species, varying in height from 12 to 24 inches, and all blooming in spring, and thriving best in a soil of peaty loam, have been introduced to Britain from New Zealand and Australia.

RENNET, or RUNNET. A liquid preparation for coagulating milk. See the articles CHEESE, MILK, and BEDSTRAW. The best rennet, and by far the most commonly used in Britain, is a peculiar infusion of the inner coat of a calf's stomach; and this is prepared in different ways in different districts, and has a diversity of power and quality dependent on the method of preparation. The Gloucestershire method, as described by Mr. Marshall, may be regarded as a fair specimen of the English methods; and the Ayrshire method, as described by Mr. Aiton, is at the same time the prevailing method throughout the Scottish Lowlands. Mr. Marshall says:—"Take the maw of a newly killed calf, and clean it of its contents, salt the bag, and put it into an earthern jar for 3 or 4 days, till it form a pickle; then take it from the jar and hang it

up to dry, after which it is to be replaced in the jar—the covering of which should be pierced with a few small holes to admit of air; and let it remain there for about 12 months. When wanted for use, a handful each of the leaves of sweet briar, dog-rose, and bramble, with 3 or 4 handfuls of salt, are to be boiled together in a gallon of water for a quarter of an hour, when the liquid is to be strained off and allowed to cool. The maw is then to be put into the liquid, together with a lemon stuck round with cloves; and the longer it remains in it the stronger and the better will be the rennet; half a pint, or less, of the liquor, is sufficient to turn 50 gallons of milk." Mr. Aiton says:—"When the stomach, or bag, is taken from the calf's body, its contents are examined, and if any straw or other food is found among the curdled milk, such impurity is removed; but no part of the chyle is suffered to be lost. At least two handfuls of salt are put into the bag, and upon its outside, after which it is rolled up in salt, and hung near a fire, where it is always allowed to hang until it is well dried, and it is understood to be improved by hanging a year, or longer, before being infused. When rennet is wanted, the 'yirning,' as it is called in Scotland, with its contents, is cut small, and put into a jar with a handful or two of salt; and a quantity either of soft water, that has been boiled, and cooled to about 65°, or of new whey taken off the curd, is put upon the bag in the jar. The quantity of water, or whey, to infuse the bag, is more or less according to the quality of the 'yirning.' If it is that of a new dropped calf, that has not been fed, 3 English pints will be enough; but if he has been fed for 4 or 5 weeks, a couple of quarts may, at least, be put on the bag to mash: it should, however, be observed that the 'yirning' of a calf 4 weeks old yields more rennet than that of one twice that age. After the infusion has remained in the jar from one to three days, the liquid is drawn off, and an English pint more water, or whey, put on the bag in the jar; and that, after standing in mash one or two days, is also drawn off, and, with that of the first infusion, strained, if any impurities appear in the liquor: the whole being put up in bottles for use as rennet, and the bag being thrown on the dunghill, without ever being put into the milk. Some put about a dram of good whisky into each quart bottle of the rennet; and it may be either used immediately, or kept for as many months as may be convenient."

RENT. The sum of services, produce, or money paid for the use of lands or tenements by the occupier to the owner. The word primarily denotes a return for advantages enjoyed; and is derived from the word *reditus* in its corrupted form of *renditus*. In feudal times, the rent of land arose out of the peculiar character of the tenure, and was paid in military services and rural labours; and in remote or primitive districts at the present day, it is controlled by the paucity of a circulating medium or by the general poverty of the agricultural community, and is paid partly or wholly in produce of the soil and in personal services. But in all enlightened, improved, and prosperous districts, even where it bears a name of produce, or is in any way determined in amount by the fluctuating circumstances of produce, it is now paid entirely in money. In an economical view, rent is either natural or covenanted; and in a legal view, it is either rent-service, rent-charge, or dry rent. A natural rent is the sum rendered due by the mere fact of occupancy, or of the raising and reaping of produce;—and is determined by the quantity of the produce, the price of the produce, the costs of cultivation, and the resulting profits of the occupier, and therefore varies every season; and a covenanted rent is the sum agreed to be paid by mere arbitrary agreement, and rests on hypotheses of the anticipated proceeds of occupancy, and may be either fluctuating or constant in amount, according to the conditions of the agreement. A rent-service is paid partly in money and partly in personal services; a rent-charge is a sum of money covenanted to be paid for occupancy of land under a clause of distress for non-payment charged on the land; and a dry rent or rent sec is the same thing without any clause of distress.

The amount of the rent of land, in general, is controlled by the wealth of the country, the number and employments and wants of its population, the distance of markets, the means of conveyance, the competition of farmers, the amount of public burdens, the price of produce, and other less important circumstances; and the amount of the rent of any particular farm, is controlled, in addition, by the nature of the soil, the condition of the fields and fences and drainage, the duration of the tenure, the conditions of the lease, the capital required to be invested in stocking and cultivation, and the peculiar or local expenses which the farmer must incur. Less rent can be paid proportionally for poor than for rich soil, in consequence of the costs of tillage and seed being nearly the same, and of both the quantity and the quality of the produce being inferior; less for any land under a short lease than for the same land under a long one, in consequence of the shortness of the time not allowing the farmer to do his best in improving the soil, and in working it up to a maximum produce; less for any land under fettering conditions than for the same land under free ones; less under circumstances of cultivation or locality or marketing which entail comparatively great current expenses than under circumstances which entail comparatively small ones; and less when the farmer has a capital barely sufficient for the current working of the farm than when he has an ample capital both for all current purposes and for the meeting of any emergency.

The amount of rent which is equitably due

from any land, or the proportion of the produce or of its value to which the landlord has an equitable title, is a question of great intricacy, and involves a vast number of variable and sometimes conflicting elements. Many attempts were made, in the times of the old routine husbandry, to reduce it to a standard and uniform rate; but even then they differed so widely in result, that some writers held one-fifth of the produce of arable land to be a fair amount for rent, while others contended for so much as one-third; and now they are made twenty-fold more conflicting, and rendered all but totally impracticable, by the great improvements which have been achieved by means of draining, irrigation, superior implements, agricultural chemistry, comprehensive rotations, and general enlightenment in all the principles of both economics and science which control the interests and practices of farming. Two farms, naturally possessing the same characters of soil and the same advantages of situation, may be in such widely different artificial conditions, that the one would be cheap at double the rent of the other; and two farmers, who have enjoyed the same routine advantages of mechanical training, or who might be pronounced equally good practical men, may differ so widely in the knowledge and control of the nice powers of improvement resulting from modern discovery, and from scientific calculation, that the one could well afford to pay a very high rent for any piece of good land, while the other might hold it at a moderate or even low rent, and nevertheless be a loser. Yet the equitable rent is clearly leviable from only the land itself, or from such attributes of it either natural or artificial as it possesses at the time of being let, and cannot, in any degree, be due from the results of either the superior intelligence, the superior industry, or the special improvements of the tenant. The simple surplus produce of land, in the state and under the conditions of its being let—or the profit which remains after the payment of all costs, and after a fair allowance for the risk and interest of capital and for the time and labour of the farmer—this alone is rent; and, when seen in such naked simplicity, it almost looks a more subtle and undeterminable thing than when complicated with all the general principles of economy and farming; for the very total produce of farms, whether as to annual amount or as to average value, is so very fluctuating as to keep the whole frame-work of society in continual vibration,—and therefore the *surplus* produce, which at one time may be no surplus at all and at another may be an overflowing one, and which at all times varies so mightily with local and peculiar circumstances, is surpassingly difficult to be forecast or precalculated, so as to be fixed beforehand in the form of rent. Yet approximations can be made; and these, to the utter exclusion of precedents, examples, and arbitrary rules, ought to guide both landlord and tenant.

"In Scotland," says Sir John Sinclair, "the following table of rent on arable farms states what is considered to be a fair proportion, where the land is cultivated:—

	Per English Acre.
1. Where land produces £10 10s. per acre per annum, one-third, or .	£3 10 0
2. Where land produces £6 12s. per acre, one-fourth, or . .	1 13 0
3. Where land produces only £4 5s. per acre, one-fifth, or . . .	0 17 0

In regard to grazing farms, they are let on principles totally different from the arable, namely, according to the quantity of stock they can maintain; and as they are not liable to the same expense of management, both the landlord and the tenant receive larger shares of the produce, than in the case of arable farms. In England, on the other hand, the husbandmen and their landlords are in a kind of partnership, in which the tenant provides all the capital, and undertakes the management of the whole concern; as a remuneration for which, and for the interest of the money he has invested in it, he is allowed, on arable land, equal to what is considered to be one moiety of the surplus, after defraying the expenses of cultivation, the taxes to which he is liable for the farm he occupies, and every other outgoing. Hay land requires much less of his attention, and for this he only obtains one-third of the surplus. But the profits of grazing, depending much on superior judgment in buying and selling stock, as well as skill in preventing or curing their diseases, the grazier is entitled to a share of the surplus fully equal to that of his landlord. It has been contended, as a general principle, that as both the expense of cultivating land, and the value of its produce, are infinitely various, a farmer ought to calculate what profit he can make on his whole farm, without entering into details; it being of little consequence to him, whether he pays at the rate of £10 or 10s. per acre, provided he makes an adequate interest on the capital invested. That is certainly a fair criterion on which a tenant may calculate what he ought to offer; but a landlord, in estimating the rent he ought to insist on, must take into his consideration the produce that his land is capable of yielding, and what proportion of it, or of its value, at a fair average, he has reason to expect, under all the circumstances of the case, which ought not entirely to depend on the exertions of a timid or penurious tenant. What are the profits to which a farmer is entitled, is a subject of much dispute. On the one hand it is contended, that the produce of land is of such universal and absolute necessity to the existence of mankind, that it is not reasonable it should yield to him who raises it more than a fair profit. On the other hand it is urged, that a farmer is entitled to be fully recompensed for the application of a considerable capital, exposed to the uncertainty of the seasons, when it is managed with economy and conducted with industry

and skill; and it has also been observed, that it is seldom more money is got by farming than an adequate interest for the capital invested. This is owing to competition, the articles produced being in numberless hands, who must bring them to market,—and necessity, the goods of the farmer, being in general of a perishable nature, on the sale of which he depends, for the payments he has to make and the subsistence of his family. To prove how moderate the profits of farming in general are, it appears from the most careful inquiries, that on arable farms they rarely exceed from 10 to 15 per cent. on the capital invested, which is little enough, considering that few employments are more subject to casualties than farming, or require more uniform attention. Some arable farmers, possessed of superior skill and energy, and who have got leases on reasonable terms, may clear from 15 to 20 per cent.; while others, who are deficient in these qualities, or pay too high rents, frequently become insolvent. In grazing farms the case is different, as they are attended with less expense of labour, and produce articles of a more luxurious description, for which a higher price will be given. Hence, in such farms, 15 per cent. and upwards is not unusual. Besides, the grazier is more of a merchant than the mere arable farmer,—is frequently buying as well as selling stock, and sometimes makes money by judicious speculations, though occasionally, from a sudden fall of stock, his losses are considerable. The grazier who breeds superior stock, and thence incurs great expense, is certainly well entitled to more than common profit for his skill and attention. It has been observed, however, that a farmer seldom makes much money, unless he is most advantageously situated in the neighbourhood of a great town, or unites with farming some other profitable employment. But those who have capital and ability adequate to the management of more than one concern, merit to be amply rewarded for their superior skill and industry."

Bayldon's mode of ascertaining the equitable rent of any ordinary piece of turnip land is to select one acre of the best in cultivation,—to value the labour, expenses, and produce through a four years' course of husbandry, of turnips, barley, clover, and wheat,—and, after taking an average of the profit, to deduct 10 per cent. for interest on the capital afloat, and set down the remainder as rent. "The same plan," says he, "may be adopted in the case of clays; and when a value is thus formed of the best and worst land on the farm, the intermediate qualities of the other fields may be readily valued by any person who understands the valuing of land. The sum of 10 per cent. on the capital expended on perishable stock, is much too low a rate of interest for such risks; and 15 and even 20 per cent. have been mentioned as not more than equal to the attention the business requires, and to the tear and wear and casualties of the concern. Some writers allow 10 per cent. for interest on capital only, and leave the farmer to find a remuneration for his time and attention from his exertions in business. The expenses and maintenance of the family are also allowed to arise from his and their industry, which would amount to 10 per cent. more. From strict inquiry and due examination, it would appear that the farmer is justly entitled to 20 per cent.;—to 5 per cent., which interest he could obtain from his money, and leave his personal attention unoccupied, to 5 per cent. for casualties, and deterioration of property in the shape of perishable stock, and to 10 per cent. for his time and exertions in the occupation. Thus, if a farmer expend £1,500 on a farm of 250 acres, he will require £75 for common interest, and £75 for casualties, and £150 for himself and family, a sum he and others may expect from devoting their undivided time and attention to any other business. On small farms, the tenants do a great part of the work themselves, and on extensive farms, their fullest attention will be required in directing and superintending. On the subject of the per-centage due from capital employed, very different opinions have been entertained; but it seems a fair and just conclusion to allow the farmer such profits as are derived from other professions, and 10 per cent. is sufficiently moderate. Five per cent. for casualties is also low enough, and the other 5 per cent. may be disputed, as it may be urged that the farmer could not engage in any other business without his capital. But if he be possessed of such a sum of money as would at 5 per cent. afford him a livelihood, he is fairly entitled to that interest from the business to which he applies it, along with an additional per-centage for his time and attention. The lowest calculation cannot be under 15 per cent., though my own opinion would allow him 20,—viz. 15 for profits on capital and time, and 5 for casualties."

Another question of great importance and of much intricacy is, whether the rent of land should be fixed or fluctuating,—or, in other words, whether it should be uniform in annual amount through a series of years, or should vary from year to year according to circumstances. It is commonly but improperly termed a question of money-rent or of corn-rent,—the fixed rent being called a money one because independent of anything but the mere terms of agreement, and the fluctuating rent being called a corn one because usually dependent for its variations on the fluctuating produce or prices of corn. It is a question of no concern to parties who take land from year to year upon a new annual valuation,—and of not very great moment to parties who take land for periods of only two or three or at most four years upon a valuation of the four preceding years' proceeds; but it possesses great consequence to tenants at will who continue to occupy, for an indefinite period, upon the same terms as in the first year of their

tenancy,—and still greater to extensive and enterprizing farmers who take lands upon leases of from ten to fourteen, and especially of from nineteen to thirty years. The natural rent of land for a single season can be calculated with a probability of sufficient accuracy to justify the offer and acceptance of a fixed sum; but the covenanted rent, for so long a period as that of almost any good leases, cannot be calculated, on the principle of a fixed sum, except in the way of the most obscure conjecture or of bold, reckless, and exceedingly dangerous speculation. The fluctuations and reverses which the agriculture of Britain has undergone, even in periods of the least disturbed progress of legislation and commerce, but especially at times of revulsion and upheaval in national politics and in international connexions, have repeatedly tossed all the arrangements of the country which were based on fixed rents into a state of chaos, and involved the pecuniary condition of a large proportion of the agricultural community in inextricable confusion or in utter ruin. In one state of things, the landlord or the tenant acquires an excessive gain, which leads to prodigality; in the opposite state of things, he suffers an excessive loss, which may prove destruction; and in either state, the harmony of interests and the consequent well-being of general society are disturbed or overthrown. In many of the best farmed districts of Britain, therefore—particularly in the north of England and the Lowlands of Scotland, where the long-lease system prevails—the adoption of a fluctuating rent, instead of a fixed one, has become pretty general and is much approved.

The chief argument in favour of a fixed rent in all cases, and against a fluctuating one in any, is that, however ill a covenanted fixed rent may be adapted to the times, or however widely it may occasionally differ from the natural or equitable rent, yet, in consequence of being a known and exact amount, it both checks and regulates the expenditure of the tenant and sets certain bounds to the expectations of the landlord. "Now as to the tenant, it appears to us that he is better enabled to regulate his expenditure by knowing the quantity, or nearly so, of his produce, say the number of stacks of wheat, which he must lay aside as rent, than by knowing the sum of money when he is yet ignorant what proportion that sum will bear to the gross return from his farm. As regards the proprietor, again, we conceive that the virtual value of his income is fully as steady when made up of produce-rents as money-rents. This results from the fact that the staple products of the country, such as corn, butcher-meat, and wool, are the chief regulators of the value of money. Thus, if the proprietor's income be regulated by these, or even by the most important of them, he may calculate on being able always to obtain out of it pretty nearly the same quantities of the necessaries and even of the luxuries of life. But even if it were some advantage in ordinary cases for both parties to know the amount of money in place of produce which they have to give and receive, such knowledge can be of little consolation to the tenant when that money becomes double of what he would give, or to the proprietor when it is only half of what he would get, were a new bargain to be made. That such cases have often happened with farms let on fixed money-rents, during the last half century, no one in the least acquainted with the history of British agriculture will deny. There appears, therefore, to be no such advantage in a constant rent over a fluctuating one, from the mere fixedness of the one over the variableness of the other, as to make us prefer the former, if the latter can be better proportioned to the means of paying it."

A fluctuating rent, however—in order to its maintaining a near approximation to a natural rent, or in order that it may not involve irregularities and disadvantages nearly as great as those of a fixed rent—must either be understood with considerable limitations, or calculated with express reference to particular farms or districts, or determined by very comprehensive principles. "The amount of rent for improvable and well-cultivated farms," remarks Sir John Sinclair, "does not depend so much on the price of grain, as is commonly imagined. A large proportion of such farms usually produce green crops, the value of which depends upon the prices of beef, mutton, and wool, and not on that of grain. Various circumstances also may arise, which may reduce the price of particular sorts of grain below its usual level (for example, barley, when the distilleries are stopped); or may raise it disproportionably much higher, in case a large proportion of the wheat crop should be destroyed by rust or mildew." In consequence, too, of depressed prices commonly proceeding from an abundant harvest, and exalted prices from a deficient one, a fluctuating rent determinable simply by the current price of corn might be lowest when the farmer has most to give and highest when he has least, so that the landlord might suffer in years of plentiful produce and low prices, and the tenant in years of scanty produce and high prices, and the interests of the two be made to work against each other to the eventual and serious injury of both.

One contrivance for checking the irregularities of the system is to make only one half of the total rent fluctuating, and to make the other half fixed; and this has been found pretty satisfactory for both tenant and landlord in most cases where a considerable portion of the total produce arises from green crops, grass, and live stock.—Another contrivance is to determine the total fluctuating rent of each year by the average of prices during the preceding seven years; and this, of course, prevents any disarrangement from any one great and sudden rise or fall in the market, but, at the same time, is no check whatever upon an aggre-

gate advance or retrogression in prices, or upon any great aggregate change in the relative values of labour and produce, during any one septennial period of a lease as compared to any other septennial period.—A third contrivance is to fix a maximum and minimum price for the particular grain, whether wheat or oats or barley, or two or all of them, by which the amount of rent is determined; and this so operates that the tenant pays no rent for any price above the maximum, and the landlord sustains no deduction for any price below the minimum.—But all these contrivances, as well as modifications of them, are mere checks, and take for granted a radical deficiency in the method of calculating the fluctuating rent, and are themselves subject, though in a much less degree, to the very same kind of irregular tendencies which they are designed to control. An incomparably better method is to calculate on such comprehensive and searching principles as shall make the fluctuating rent always coincide with the natural or equitable rent, or as shall cause it to vibrate in perfect accordance with the aggregate surplus productiveness of the farm; and this would, no doubt, have been everywhere adopted from the beginning, if the requisite principles for truly determining the rent could have been found,—and will readily be adopted still if the principles can now be satisfactorily made out. We therefore gladly transfer to our pages what we think an important approximation to them, in an able article of the Journal of Agriculture, published in January, 1846:—

"It is clear that either acreable quantity of produce, or price of produce, or both together, are the facts to be taken as the regulators of the fluctuations of rent. We fix upon these, because, among other reasons, the expense of cultivation and the profit due to the tenant, though equally important with these in determining rent, are subject to much smaller and less sudden fluctuations, so that their influence can be more easily estimated beforehand. Before discussing, however, whether both these facts regarding produce (viz., acreable quantity and price) should form the basis of fluctuating rents, several intermediate inquiries suggest themselves.

"Of these the first is—Can we carry the principle of fluctuation so far into practice as to make the portion of the rent fluctuate which is dependant upon animal as well as that which is dependant on vegetable produce? The entire rent of a farm is sometimes regulated by grain, on the plea that the price of stock usually fluctuates in accordance with that of grain. A correspondence, more or less close, between the two may, no doubt, be observed over an average of several years, yet there is often, perhaps generally, such a discrepancy between their fluctuations in one or two seasons, as would render a rent calculated from the one a very false representative of that naturally payable from the other. The rent payable from stock, therefore, ought not to be regulated by grain. The regulation either from the value of stock or from the acreable value of the crops which produce the grain, is evidently the natural expedient. The former of these, for many reasons, would be extremely difficult to determine satisfactorily. One of the most obvious reasons is the universal practice of selling cattle by dead weight, which is estimated merely by the eye. Then there are so many different breeds of cattle brought into the market, and in so very different stages of ripeness, that it would be difficult to fix their average value. Still it seems possible to estimate judicially an average on the price of stock sold in the principal markets, and the average of such markets as Smithfield would form a good criterion of the price of fat stock. But we must here apply by anticipation to stock-rents, a principle which we shall afterwards expound as a fundamental one of all fluctuating rents. By this principle we conclude that, if such rents are to fluctuate, it ought not so with the price of stock merely, but also with the quantity produced. The average acreable value of stock-feeding crops is, therefore, the fact, rather than the average price per stone of beef, mutton, or wool, which ought to be determined to regulate fluctuating rent payable from stock. Turnips, grass, and other stock-feeding crops being often sold by the acre, we see no impossibility in determining their acreable value in a similar way as grain-crops. But as we consider the application of the above principle to the rent from grain of the most importance, and there is, as yet, little prospect of that being effected, we need not here press the further extension of the principle. We therefore conclude that there is no immediate prospect of making the portion of rent dependant on animal produce fluctuate on a proper principle.

"This being the case, our next inquiry is—How ought the rent, payable from stock, the constant portion, to be proportioned to the whole rent? This depends on the rotation of cropping followed, as it regulates the proportion of income derived from stock; but even with a knowledge of the rotation, it is exceedingly difficult to determine this point. A perfect separation, indeed, of the two sources of rent is impossible, even by inspection of the most accurately kept accounts. This arises from a great part of the produce of one source being made to promote that of the other without a valuation being possible; and besides the difficulty of estimating accurately the value of straw, dung, &c., thus passing from one member of the rotation to another, it is still more impossible to say exactly what proportion of the expense of labour ought to be charged against each. We are inclined to think, however, that the benefits mutually given and received by the grain and stock-feeding crops, ought, under proper cultivation, to be pretty nearly balanced, and that the share of the expense which ought to be charged against each is nearly in proportion to the gross return yielded by each. On this supposition, the share of the rent determined from the average value of stock, (or fixed at a sum of money, if no such value has been judicially determined,) and that from grain, ought apparently to be in proportion to the gross return from sales of stock and of grain. This conclusion, however, must be modified by the consideration that the money obtained for stock is the return from a proportionally larger capital than that obtained from grain, and therefore its proportion for rent ought to be less. On this account, in place of taking the gross return from sales of stock, the value that would be obtained by selling the stock-feeding crops to be eaten on the premises ought to determine their portion of the rent. This mode would have the advantage of being a simpler guide than the value of the stock sold in any year, because that seldom corresponds exactly with the money received for them. In making an offer, therefore, of a rent partly constant and partly fluctuating, for a farm intended to be cultivated on a certain rotation, an estimate would first require to be made of the average value in several previous years of its grain and stock-feeding crops. The average sum thus naturally payable out of these taken together would then fall to be com-

puted as rent. This average might then be adopted as the supposed average of future years, or at least it would afford data from which the future average natural rent might be formed. The sum, then, to be fixed as the constant part of the rent, representing that dependant on stock, ought to bear the same proportion to the supposed entire future average natural rent as the value of the stock-feeding crops bears to the value of the whole produce of the farm. The portion of the rent thus payable for stock must, of course, be much less where bare fallowing is practised than where the whole fallow division bears a crop.

"We have now to inquire—What is the species of grain by whose acreable quantity or price, or both, the fluctuating portion of rent is likely in future to be chiefly regulated? All the grain and also pulse crops (which in this case may be classed together) ought properly to enter into this calculation in the proportion in which they are intended to be grown on the farm in question; yet, as the prices of all sorts of grain fluctuate pretty much in unison, fluctuating rents are sometimes regulated by the most valuable grain alone, provided it is the chief product of the farm, since it is at the same time the product whose price most influences that of other commodities, as also the rate of wages, &c. We do not mean to recommend this practice, yet, in justification of it, we may state that by the average imperial prices of wheat, barley, and oats, from 1771 to 1842 inclusive, as given in M'Culloch's Commercial Dictionary from parliamentary returns, we find that the fluctuation in the relative prices of these is very small when compared with the immense fluctuations in the absolute price of each. Within the period above mentioned, the price of wheat fluctuated about 364 per cent., that of barley 391 per cent., and that of oats 314 per cent. The fluctuations, on the other hand, in the relative prices of these grains within the same period scarcely amounts to 100 per cent. Comparing the price of barley with that of wheat, we find that the former was always more than one-third, and only once reached two-thirds of the latter; and comparing oats with wheat, we find that the former was always more than one-fourth, and never reached one-half, the price of the latter. The fluctuations in the relative prices of these grains, though very considerable, being thus much less important than the absolute fluctuations of each, the assumption of the species chiefly grown as the representative of the whole, in annually regulating the rent, ought to be a smaller source of error than in following the price of any, or all of them, in past years, in fixing the rent during a long series of future years. This latter course is followed in fixing a constant money-rent. It need not, therefore, appear objectionable if, for simplicity and other reasons, one species of grain should be taken as the sole basis of calculation of a fluctuating rent, where such species greatly predominates as a marketable product of the farm. At all events, it cannot be out of place to inquire here what ought to be regarded as the most important grain product of the country, whether with a view of its being the sole or (on a more accurate system) the chief regulator of the fluctuating portion of the rent of good arable land. Wheat has hitherto held this place. Let us therefore examine whether there is any likelihood of a change in this respect. A very common conclusion in the complaints of farmers of late years of a fall in the value of agricultural produce, has been the expression of the opinion that they cannot afford to grow wheat below a certain price, usually the lowest they have experienced up to that time. Nor is this merely a vague mode of talking; for such an opinion has been maintained on oath by many of the most eminent agriculturists of the country. Thus, before the parliamentary committee on agricultural distress in 1836, when prices were much the same as they were in the early part of this season, almost every witness stated that a price of wheat varying from 40s. to 65s. per quarter according to locality, rent, skill, and other circumstances, was that below which he considered he could not afford to cultivate it; and many distinctly stated that, should it fall below that price, its cultivation must be abandoned for other grains. Now, though we deprecate any measure tending, by great and sudden reduction in the price of grain, to throw part of the land now so employed into pasturage, and thus diminish the quantity of farinaceous human food, yet we cannot enter into those views which would deter us from the cultivation of wheat only. We see no reason, from the experience on the subject alluded to, or on any other ground, to expect wheat to fall in price without a somewhat proportionate fall in the prices of other grains. Now supposing our three chief kinds of grain to continue to bear the same ratio in price which they bore on an average during the period above spoken of, the return from the cultivation of them on land well suited for each would be as follows:—

Wheat.
63s. per quarter.
4 quarters per acre.
252s. per acre.

Barley.
33s. per quarter.
5 quarters per acre.
165s. per acre.

Oats.
23s. per quarter.
6 quarters per acre.
138s. per acre.

These prices may be considerably more than can be calculated on for the future, but their proportion to each other cannot be greatly altered; wheat ought always to yield the greatest return. But it may be objected that wheat is the most exhausting crop. We answer that it is at the same time the most restorative crop; because, while the quantity of grain, the only part not returned to the land, is less bulky from wheat than from barley and oats, in the proportion of four to five and six, its straw is more bulky in nearly the same ratio. If the argument against wheat be put in another shape, and it be said that it incurs more expense both in work and manure than any other crop, we ask what does this objection amount to? Merely to this—That wheat (except after grass) must be preceded by a highly manured fallow—either a bare fallow, which pays nothing, or turnips, potatoes, or other drilled crops, which often scarcely pay. Admitted. But are not fallowing and manuring necessary to keep the land clean and in proper condition, whatever sort of crop may follow—necessary for good grass, which, again, must carry good stock, that the following oat-crop may also be good—not to speak of the direct benefit which the succeeding crops may derive from the fallow-applied manure still inert in the soil? This reasoning, with some alteration of terms, applies as well to every course of cropping as to the five years course which we have had in view. If, then, such a system of cultivation is necessary for other crops as well as wheat, it is surely absurd to say that the crop which gives the greatest return for the outlay is the one which only cannot be afforded to be grown. It would be as reasonable for a fisherman who had to keep up his full establishment of men, boats, and nets, to say that he could not afford to catch the most valuable sort of fish. Thus we believe, in

contra-distinction to the often-expressed opinion of the farmers themselves, that wheat will continue to bear as high a proportion in price to other grains as it bears at present, however much the cultivation of all may increase or diminish. In truth, we rather expect to find the proportion of wheat becoming every year greater on account of its being sown more generally after turnips, and of the extended tillage of the old grass-land of England, most of which is admirably adapted for wheat. On these grounds, then, we are of opinion that wheat is likely to continue to form the chief basis for calculating the fluctuating grain-rents of good arable farms.

"We have now arrived at this point of our inquiry—Whether ought the fluctuating or grain rent to be regulated by the average price alone, or by the average both of price and acreable quantity of grain produced throughout the district or county? We have already anticipated, so far, the answer to this question, by stating that, in the case of the share of rent payable from stock, if the rent is to fluctuate, it ought to fluctuate both with the average price and the quantity of stock, or of stock-feeding crops. Price alone, however, has hitherto been attended to in regulating grain-rents. This we consider to be a glaring defect in the system now followed, as applied to the present, and more especially to what we hope will be the future state of our grain markets. We consider such a system in many instances to be unfair to the proprietor and in others to the tenant. It is unfair to the proprietor when the crop of the county, and therefore, presumably, that of his own property, exceeds the average quantity of many years' crops in a greater degree than its price falls below the average, and for the tenant, when the crop falls under an average quantity to a greater degree than its price rises above the average. But, suppose the fluctuations in price to be exactly the reverse of the fluctuations in quantity, the present method is far from being a proper one for adjusting rent; because, were the price to fall in the same proportion as the acreable produce increased, the tenant ought still to have the same income from his farm, which being obtained at a smaller outlay, he would have a greater balance to pay rent from a large cheap crop than from a small dear one. Hence the present system of grain-rents is particularly unfavourable for the landlord when the crop is abundant and cheap, and equally so for the tenant when scanty and dear. Its only proper and justifiable tendency seems to be, to give the proprietor a share in the benefit from a rise in prices, when the rise is not produced by a deficiency of crop, and to protect the tenant against the entire loss from an unlooked-for reduction of price through an inundation of foreign corn. The extraordinary fluctuations in the price of grain in this country during the continental war were not caused entirely, or even chiefly, by corresponding variations in the quantity raised. The immense rise in price, on some occasions, was caused partly by bad harvests, but still more by the fear of their recurrence, whilst foreign supplies were almost entirely excluded, and by speculators being thus induced to diminish the supply for immediate consumption by storing grain. The sudden and great fall in price on more recent occasions was caused by the abundant home supplies being rendered still more abundant by a sudden opening up of foreign traffic. The prices of grain, under both these circumstances, and similar circumstances have happened in earlier periods of our history, varied much more than the quantity produced. The rent naturally payable, therefore, often depended more on the price than on the quantity, so that the regulation of fluctuating rents by the average price was the natural means to resort to. This system was adopted, and, no doubt, saved many a farmer from ruin, after the conclusion of the war, and where adopted, then, secured to landlords a fair share of the rise in the markets occasioned by the war. Having thus far supplied the necessity which called it into existence, the present system of grain-rents is gradually becoming less popular—people are beginning to think that the most natural state of the relation between landlord and tenant is to pay most for the use of land only when it produces the most abundant crops. Various modifications have been introduced in the mode in which the system of grain-rents acts; but they are all merely empirical cures for the evil, and founded on no sound principle. We, therefore, come to this conclusion—That unless both the first and second foundations of rent above laid down, that is, unless the county average of the acreable quantity, as well as that of the price of the regulating grain, be taken as an element in the calculation of fluctuating rents, these can never be properly adjusted. Indeed we conceive that, if one of the fundamental facts only is to be acted on, it ought in future to be rather the acreable quantity than the price of grain. We found this opinion on the consideration that there is a tendency more and more towards a free trade in corn, and that the more our markets are thrown open to the competition of agriculturists, from all climes and counteracting states of weather, the more steady should be the state of the markets; while we cannot suppose that the quantity we ourselves produce will by that competition be rendered more constant. We would by no means, however, be understood to propose that the quantity of produce should be taken as the sole regulator of fluctuating rents, but merely to predict that it will at some future period become a more important element than price in determining rent. The adjustment we propose is the number of bushels of grain forming the grain-rent, convertible into money by the judicial average price that should bear a constant proportion to the number of bushels per acre of the same sort of grain grown in the same year throughout the county. Such an adjustment of rents would have afforded an inexpressible consolation to farmers under the sad prospect forced upon them by the destructive rains in the month of July last. Then every farmer had the prospect of his income from the crop on the ground being much reduced; but tenants bound to pay in rent the price of fixed quantities of grain then felt the additional grievance of having their rents increased nearly in proportion to the destruction of their crops. They, we conceive, would have sufficient cause to deplore such a destruction, even were their rents slightly diminished on account of it. By the adjustment we have proposed, this diminution could only be slight; for the price of grain must always be increased by a failure of the crops, though by importation from abroad the increase may be prevented, being proportionate to the deficiency in the quantity produced. Thus landlords can have no ground of complaint, since their share of the calamity would be small.

"The arrangement proposed would give the proprietor and tenant their just shares of profit and loss from the general improvement of agriculture, without influencing the gain or loss due to the tenant for his peculiarly good or bad management. When his land is let on a constant money-rent, the proprietor's only benefit from the increased produce of the country, on account of general improvements in agriculture, depends on the frequent disproportionate increase in the value of money. When, on the other hand, it is let on the present mode of grain-rent, an increased produce by such means is rather a loss than a gain to him, by its reducing the price of grain more than that of other commodities, and consequently lowering his rental more than it raises the value of money. We see no reason why the proprietor should not share with his tenant in the varia-

tion of the productiveness of the soil, whether occasioned by the weather or by the application of science, as well as in the variation of prices. By this mode of paying rent, landlords would also derive the additional advantage of choosing skilful tenants, who, by increasing the produce of their farms would raise the average produce of the district, and consequently establish the means by which their rents would be increased. An inestimable benefit would result to the community from the adoption of this practice, by giving proprietors a more immediate pecuniary interest in increasing the produce of their estates and of the country around them, as also by its thus creating a strong inducement for them to reside on their estates. It may be objected that, by reducing rent as the average produce diminishes, there would a premium on bad farming be established. Such would be the case were the rent merely to vary with the produce of the farm for which it is paid; but when it is mainly dependant on the produce over a large district, the objection does not hold; for the influence of a scanty crop of one farm in reducing the average of the district would be so small, and the loss from it to the farmer so great, that the increasing productiveness of his farm would be as much an object to him under this as any other system of payment. It would thus present no temptation to relax his energies. One of the strongest arguments in favour of this particular system of fluctuating rents is, that, by proportioning their income to the state of the country, such a mode of rents would deprive proprietors of the most plausible argument against granting leases, and would, therefore, induce the practice with its numerous good consequences to be greatly extended. On these and other grounds, which it is unnecessary to state, we conclude that fluctuating rents ought to be regulated by the average both of price and acreable produce of grain throughout the county.

"We must now inquire, How can the annual average acreable produce of grain in each county be ascertained? The difficulty of determining this statistical fact is the only considerable obstacle to the reduction of this theory of grain-rents to practice; yet, though we cannot suggest any perfectly unobjectionable means for effecting the object, we are confident that, were the country generally as much convinced as we are of the many important uses (besides the regulation of rent) to which this information might be applied, means would soon be used for obtaining it. Sufficiently accurate data might perhaps be obtained by examining, on oath, a number of farmers from every parish in each county, on the average number of bushels of grain per acre grown on their farms in the previous season, in the same way as they are examined on the prices for which their grain is sold. Farmers would have no more difficulty in keeping an account of the quantity than of the price, and there would be as good a check on their statements of the quantity obtained as of the price for which it was sold. The maintenance and raising of their characters as agriculturists would, without any other check, be sufficient to prevent farmers from understating the acreable amount of their crops. We must, however, notice an objection which will very readily be urged against any such inquiry. It will be considered at first as of too inquisitorial a nature, and the disclosure of the rate of produce on individual farms will be said to be taken advantage of by landlords in reletting them, to the prejudice of the tenants in possession. Such a disclosure might be avoided before the public. At any rate, each witness would only be called on to disclose, at long intervals, the return from his farm, perhaps not more than twice or thrice during his lease. But even if a more ample disclosure were required, tenants would have much less ground of complaint against this than against the disclosure of their whole means and substance for the poor's-rate assessment, or that exacted of every class but themselves in respect of the income-tax act, and of which they complain of not being allowed to do in the same way as others."

REPRODUCTION. See PROPAGATION.

REPTILES. In the Linnæan arrangement, the class of cold-blooded vertebral animals which breathe by lungs, *amphibia*, consisted of two orders,—*reptilia*, having four feet, as the tortoise, frog, lizard, &c., and *serpentia*, having no external organs of motion. In Cuvier's classification the class of *reptilia* corresponds nearly to the *amphibia* of Linnæus, and is divided into the four orders of *chelonia*, tortoise, turtle,—*sauria*, crocodile, lizard, chameleon,—*ophidia*, serpents, boa, viper,—*batrachia*, frog, salamander, proteus, siren. Reptiles are distinguished from birds and quadrupeds by their cold blood and single heart (with only one ventricle), and from fish by their respiring through lungs. Their blood is never at a much higher temperature than that of the medium in which they live. No other animals are capable of enduring so great extremes of heat and cold as the reptiles, especially some particular species: frogs, for instance, have continued to live in the human stomach, and in lumps of ice. From the peculiar structure of their bodies, they are able to suspend their respiration for a considerable time, and are also endowed with the faculty of enduring an abstinence that would prove fatal to warm-blooded animals. Most of them can live in the air as well as in water. Many live indifferently in either element. Some pass a certain period of life, or certain seasons of the year, in one, and the rest in the other; and some, finally, are confined to the water, or to the land. They live chiefly in morasses, swamps and stagnant waters, damp, dark places, caves, and holes in the earth. As means of defence, nature has given to some of them great bodily strength, or sharp teeth, as to the crocodile; to others a deadly poison, as to certain kinds of serpents; to others a hard covering, as to the tortoise; to many a disgusting smell, or an acrid humour, which they eject. Some of them have a remarkable power of reproduction, by which they renew parts of the body of which they have been deprived. Some can live for an incredibly long time without air, and even without food, and some undergo transformations like insects. None of them chew their food, but they swallow it whole, and digest it at leisure. They are in general extremely tenacious of life, and will continue to move, and perform other animal functions, even after the severest injuries. Their colours and general appearance are, in most instances, disagreeable: some, however are decorated with the most vivid colouring. Their voices are either harsh and grating, or they are entirely dumb. Most reptiles are oviparous. In some, particularly in the frogs, the

eggs are not fecundated until after their expulsion from the female; hence they are merely provided with a thin membranous covering. The eggs of others, as the tortoise's, have a soft, tough skin, resembling parchment, while, in other genera, the eggs are furnished with a hard, calcareous shell. In those species which are viviparous, the eggs are regularly formed, but are hatched internally, as in vipers, &c.

The following arrangement of the *reptilia* is that given by the prince of Musignano; and, although it presents points of objection, these are as few as in any other attempt of the kind; added to which it is the latest:—

CLASS.

REPTILIA.

FIRST SUB-CLASS.

PULMONEA.

ORDER I.

CHELONII.

FIRST FAMILY.

TESTUDINIDÆ.

a Testudinina.

1. Testudo, *L.*
   Sub-genera, 3.
2. Terrapene, *Bonap.*
3. Kinosternum, *Bonap.*
4. Emys, *Bonap.*
   Sub-genera, 2.
5. Hydraspis, *Bell.*
6. Chelonura, *Flem.*

b Chelydina.

7. Chelys, *Dumer.*

c Trionicina.

8. Trionix, *Geoff.*

SECOND FAMILY.

CHELONIDÆ.

a Sphargidina.

9. Sphargis, *Merr.*

b Chelonina.

10. Chelonia, *Brong.*

ORDER II.

SAURI.

THIRD FAMILY.

ICHTHYOSAURI.

11. Teleosaurus, *Geoffr.*
12. Steneosaurus, *Geoffr.*
13. Ichthyosaurus, *Koenig.*
14. Saurodon, *Hays.*
15. Plesiosaurus, *Conybeare.*
16. Geosaurus, *Cuv.*
17. Megalosaurus, *Buckland.*

FOURTH FAMILY.

CROCODILI.

18. Crocodilus, *Cuv.*
    Sub-genera, 3.

FIFTH FAMILY.

LACERTIFORMES.

FIRST SUB-FAMILY.

LACERTIDÆ.

a Tupinambina.

19. Varanus, *Merr.*
    Sub-genera, 4.
20. Teius, *Merr.*
    Sub-genera, 6.

b Lacertina.

21. Lacerta, *L.*
    Sub-genera, 2.
22. Tachydromus, *Oppel.*

SECOND SUB-FAMILY.

STELLIONIDÆ.

a Agamina.

23. Uromastix, *Cuv.*
24. Cordylus, *Gronov.*
25. Stellio, *Daud.*
    Sub-genera, 2.
26. Agama, *Daud.*
    Sub-genera, 15.
27. Lophura, *Gray.*
28. Draco, *L.*
    Sub-genera, 2.
29. Pterodactylus, *Cuv.*
30. Chlamydosaurus, *Gray.*

b Iguanina.

31. Iguana, *Cuv.*
32. Ctenosaura, *Wiegm.*
33. Ophryessa, *Boie.*
34. Leiocephalus, *Gray.*
35. Basiliscus, *Daud.*
36. Polychrus, *Cuv.*
37. Ecphimotes, *Fitzinger.*
38. Ophlurus, *Cuv.*
39. Anolius, *Cuv.*
40. Mosasaurus, *Conybeare.*
41. Iguanadon, *Mantell.*

THIRD SUB-FAMILY.

GECKOTIDÆ.

42. Cirtodactylus, *Gray.*
43. Euplephoris, *Gray.*
44. Phyllurus, *Gray.*
45. Gymnodactylus, *Spix.*
46. Stenodactylus, *Cuv.*
47. Spheroidactylus, *Cuv.*
48. Ptyodactylus, *Gray.*
49. Phyllodactylus, *Gray.*
50. Thecadactylus, *Cuv.*
    Sub-genera, 4.
51. Hemidactylus, *Gray.*
52. Platydactylus, *Cuv.*
    Sub-genera, 6.

FOURTH SUB-FAMILY.

CHAMÆLEONIDÆ.

53. Chamæleon, *Daud.*

FIFTH SUB-FAMILY.

SCINCIDÆ.

54. Scincus, *Daud.*
    Sub-genera, 3.
55. Gymnophthalmus, *Merr.*
56. Spondylurus, *Fitz.*
57. Heteropus, *Wiegm.*
58. Gerrhosaurus, *Wiegm.*
59. Gerrhonotus, *Wiegm.*
60. Trachysaurus, *Gray.*
61. Cicigna, *Gray.*

SIXTH FAMILY.

ANGUIDÆ.

* Tetrapodi.

62. Seps, *Daud.*
    Sub-genera, 5.
63. Chalcides, *Daud.*
    Sub-genera, 4.

** Bipedi.

64. Bipes, *Lacep.*
    Sub-genera, 2.
65. Chirotes, *Cuv.*

*** Apodi.

a Anguina.

66. Pseudopus, *Merr.*
67. Ophisaurus, *Daud.*
68. Anguis, *L.*
69. Acontias, *Cuv.*

b Amphisbænina.

70. Typhlos, *Schn.*
71. Amphisbæna, *L.*
    Sub-genera, 2.

ORDER III.

SERPENTES.

SEVENTH FAMILY.

OPHIDII.

FIRST SUB-FAMILY.

COLUBRIDÆ.

a Ericina.

72. Anilius, *Oken.*
    Sub-genera, 2.
73. Erix, *Daud.*
74. Clothonia, *Daud.*

b Boina.

75. Boa, *L.*
    Sub-genera, 2.
76. Python, *Daud.*

c Colubrina.

77. Erpeton, *Lacep.*
78. Scytale, *Merr.*
79. Coluber, *L.*
    Sub-genera, 13.

d Acrochordina.

80. Acrochordus, *Hornstedt.*

SECOND SUB-FAMILY.

HYDRIDÆ.

a Bungarina.

81. Bungarus, *Daud.*
82. Ophis, *Wagler.*

b Hydrina.

83. Hydrophis, *Daud.*
    Sub-genera, 4.
84. Disteria, *Lacep.*
85. Aipysurus, *Lacep.*

THIRD SUB-FAMILY.

VIPERIDÆ.

a Viperina.

86. Vipera, *Daud.*
    Sub-genera, 4.
87. Sepedon, *Merr.*
88. Naja, *Laur.*
89. Elaps, *Schw.*
    Sub-genera, 2.
90. Platurus, *Latr.*

91. Trimeresurus, *Lacep.*
92. Oplocephalus, *Cuv.*
93. Acanthophis, *Daud.*
94. Echis, *Merr.*
95. Langaha, *Brug.*

b Crotalina.

96. Trigonocephalus, *Oppel.*
Sub-genera, 4.
97. Crotalus, *L.*
Sub-genera, 2.

Eighth Family.
CŒCILIDÆ.

98. Cœcilia, *L.*

Second Sub-Class.
AMPHIBIA.

Order IV.
ANOURA.

99. Hyla, *Laur.*
Sub-genera, 4.
100. Rana, *L.*
101. Megophrys, *Kuhl.*
102. Ceratophrys, *Boie.*
Sub-genera, 2.
103. Dactylethra, *Cuv.*
104. Breviceps, *Merr.*
105. Bombinator, *Merr.*
106. Pipa, *Lauren.*
107. Bufo, *Lauren.*
108. Rhinellus, *Fitz.*
Sub-genera, 3.

Tenth Family.
URODELA.

109. Salamandra, *Lauren.*
Sub-genera, 3.
110. Triton, *Lauren.*

Order V.
NULLIBRANCHIA.

Eleventh Family.
AMPHIUMIDÆ.

111. Protonopsis, *Barton.*
112. Amphiuma, *Garden.*

Twelfth Family.
SIRENIDÆ

a Proteina.

113. Axolot, *Cuv.*
114. Proteus, *Laur.*
115. Necturus, *Rafinesque.*

b Sirenina.

116. Siren, *L.*
Sub-genera, 2.

RESEDA. A genus of thalamiflorous plants, nearly allied to the Cruciferæ, but differing from them in the stamens being indefinite, the capsules unilocular, and the seeds without an umbilical cord; and it constitutes an order of its own under the name of Resedaceæ. One species grows wild in Britain; and upwards of 20 species have been introduced from Continental Europe, Africa, and the Levant. But only two species possess any considerable interest; and these are noticed in the articles Dyer's Weed and Mignonette.

RESERVOIR. A contrivance for accumulating and retaining meagre supplies of water. The chief kinds of it required for agricultural purposes are the pond and the dam. See the articles Pond and Embankment.

RESIN. A vegetable substance, which exudes from many trees, either from natural fissures or artificial wounds. Common resin, or rosin, is obtained by distilling the exuded matter of some species of pine; oil of turpentine passes over, and the resin remains behind. The resins are insoluble in water, but soluble in alcohol, and inodorous, though they sometimes derive odour from containing an essential oil. They consist chiefly of carbon, with about one quarter of oxygen and hydrogen.

RESP. See Red Water.

RESPIRATION. The alternate inspiration and expiration of atmospheric air, for the purpose of bringing it into contact with the blood, and exchanging the hydrogen and carbon with which it is charged, for oxygen. This function is therefore closely connected with that of the circulation of the blood. The organs and mechanism by which this wonderful function is carried on, vary considerably in the different classes of animals. In the mammalia, birds and reptiles, the organ of respiration is the lungs; in fish, the gills; in most insects, the tracheæ; and in the lower classes of animals, different parts of the system. The air, being brought into contact with the blood, is decomposed, its oxygen is united with the blood, and its nitrogen is returned by expiration, unchanged, with an addition quantity of carbonic acid gas. A part of the oxygen of the inhaled air is united in the lungs with the free hydrogen, and forms water, which is emitted in the form of vapour, visible at 40° Fahr. Another part of the oxygen unites with the superfluous carbon in the blood, and forms the carbonic acid gas, which passes off with the watery vapour. It is evident from observation, that oxygen gas is necessary to animal life. As to its manner of operating in the body after inspiration, opinions differ. Upon respiration depends also animal heat, which is greater, at least in the mammalia and in birds, than that of the surrounding element. The mechanical part of the function of respiration is effected by the action of the ribs and diaphragm. In the natural state, the ribs are inclined downwards, and when this series of moveable hoops is raised by the action of the muscles, the cavity of the chest is enlarged. The descent of the diaphragm by its contraction increases this effect, and the air therefore rushes in to fill up the vacant space; the ribs then descend, and the diaphragm rises, and the air is necessarily driven out in consequence of the resulting contraction of the chest. About twenty respirations take place in a minute, and from thirty to forty cubic inches of air are inhaled at each inspiration. A man consumes about a gallon of air in the same time.

RESTHARROW,—botanically *Ononis.* A diversified genus of plants, of the lotus division and genista subdivision of the leguminous order. One species grows wild in Britain; about 60 species have been introduced from other countries; and about 50 other species are known. About one half of the introduced species have yellow flowers; and most of the others have either pink or purple flowers. Some are evergreen undershrubs; some are annuals; a few are creepers; and a few are radical herbaceous perennials.

Some have simple leaves, and others trifoliate leaves; some axillary flowers, and others sessile or subsessile flowers; and most have a height of between 6 and 24 inches. Some are said to be grateful to asses, and hence got the name of ononis or "ass-delighting;" and about one-third or so are more or less ornamental.

The cammock, or spring restharrow, or field restharrow, *Ononis spinosa*, or *Ononis arvensis*, is a perennial-rooted indigen of sea-shores and fields and other situations in Britain. Its root is strong, and resists the action of the harrow's tines, and hence gave rise to the popular name restharrow; its stems are hairy, somewhat woody, and commonly about 12 inches high,—yet are very various in length; its leaves are generally simple and entire towards their base; and its flowers are mostly solitary, large, handsome, and of a bright flesh colour, and bloom from June till August. A variety of it, found in a wild state, has white flowers.

The shrubby restharrow, *Ononis fruticosa*, is a native of the south of France, and was introduced to Britain in the latter part of the 17th century, and has long been well known in British shrubberies and gardens. It is a hardy, handsome, evergreen shrub, of about 2 or 3 feet in height. Its branches are numerous and slender, and have a purplish brown bark; its leaves are trifoliate, and come out irregularly on the branches, and sit close, and are narrow, lanceolate, and serrated; and its flowers come out in panicles from the ends of the branches,—and stand on long footstalks, generally three on one,—and are large and pinkish red,—and bloom in May and June; and its pods are short and turgid, and ripen their seeds in July or August.

RESTIO. A genus of monocotyledonous plants, constituting the type of the natural order Restiaceæ. This order is nearly allied to the sedges and the rushes; and consists of rigid, weedy, coarsely grassy looking plants, many of them leafless; and occurs only in the southern hemisphere, and principally in Australia and Southern Africa. Four or five hardy species, 3 or 4 stove species, and nearly 30 greenhouse ones have been introduced to the botanical collections of Britain; and about one-third of the last,—chiefly about 3 feet high, some with simple culms, and some with branched culms,—belong to the genus restio; but all are more curious than either beautiful or useful; though some of the Cape-of-Good-Hope ones are used in their native country for making cordage, and thence occasion the genus to be sometimes popularly called rope-grass.

RESTIVENESS. A well-known, most annoying, and very dangerous vice in some horses. It may sometimes be modified by particular treatment, or restrained by peculiar circumstances, or temporarily subdued by smart and dexterous discipline; but scarcely ever or at all can it be conquered or even permanently alleviated. "It is a rule that admits of very few exceptions," remarks Youatt, "that he neither displays his wisdom nor consults his safety who attempts to conquer a restive horse."

REVOLVING HARROW. See Grubber.

REY-GRASS. See Rye-Grass.

RHABDOCHLOA. A genus of exotic grasses, of the chloris tribe. Three species—all annual, about a foot high, naturally blooming in July and August, very handsome in appearance, and capable of being grown in the open ground, in any ordinary soil,—have been introduced to British collections from the West Indies and North America.

RHAMNUS. See Buckthorn.

RHAPONTICA. A genus of ornamental, hardy, perennial-rooted, purple-flowered, herbaceous plants, of the thistle division of the composite order. Three species, varying in height from 1½ to 3 feet, and all blooming in July and August, and thriving well in any ordinary soil, and nearly allied to the centauries, have been introduced to Britain.

RHEUM. See Rhubarb.

RHEUMATISM. Inflammation of the cellular coat of the muscles, or of the ligaments and synovial membranes of the joints. It was formerly supposed to arise from a defluction of humours to the joints; and it thence acquired its name of rheumatism,—from a word signifying a fluxion or humour.

Rheumatism in the horse is denied by some veterinarians, and was not long ago denied by almost all, yet is really very common. It arises from exposure to cold and rain, especially after being heated with exercise,—from washing the limbs with cold water when they are heated and perspiring,—and, in general, from most of the causes which induce catarrh and influenza; and it most readily attacks young horses who are severely worked, and old ones who have lived a life of coarse treatment or of hard labour. It is sometimes indicated by swelling and perceptible tenderness; but, in general, it shows itself by mere lameness, accompanied always with expression of acute pain, and sometimes with a considerable degree of feverishness. Whenever lameness, after a careful examination, cannot be accounted for, or is found to go off after exercise and to return again, it may pretty certainly be pronounced rheumatic. It is, in all cases, distressing,—in many, obstinate,—in some, a kind of torturing palsy,—and, in most, capable of great alleviation, and even of a real and permanent cure. The remedies for it are bleeding, moderate purgings, fomentations, stimulating embrocations, and somewhat warm and uniform temperature.

Rheumatism in cattle is much more frequent than in horses; and arises from the same causes as in man, or from the same which produce common colds; and is particularly prevalent in cold, marshy, bleak situations, and during great and

sudden changes of weather in spring and autumn; and is in some instances acute, and in others chronic,—in some continuous and accompanied with fever, and in others occasional or fitful and indicated chiefly by stiffness and lameness and expressions of pain. It may generally be palliated, but can rarely be cured. The remedies for it are shelter, warmth, aperients, diaphoretics, stimulating embrocations, and anodyne action both internally along with the aperients and externally along with the embrocations.

Rheumatism in sheep is similar in at once causes, symptoms, and character, to rheumatism in cattle. Any sheep affected with it should be removed to a comfortable shed, and receive a warm aperient, and be rubbed over the affected part with opodeldoc or hartshorn liniment; and, if the disease become chronic, a seton should be inserted near the affected part.

RHEXIA. A genus of ornamental, exotic plants, of the melastoma family. The Maryland species, *R. mariana*, was introduced to Britain from North America about 90 years ago; and is a handsome, hardy, purple-flowered, radical herbaceous perennial of about 9 inches in height; and comprises a variety with pink-coloured flowers. Five or six other species have been introduced.

RHINANTHUS. See Rattle (Yellow).

RHIPSALIS. A genus of exotic plants, of the cactus order. Seven or eight species, mostly about a foot high, have been introduced to British collections, and are propagable from cuttings. See the article Cactus.

RHIZOBOLUS. See Butter-Nut.

RHIZOMA. See Orchis.

RHIZOPHORA. See Mangrove.

RHODANTHE. A recently discovered genus of ornamental plants, of the composite order. Captain Mangles's species, *R. Manglesii*, is one of the handsomest half-hardy annuals at present cultivated in British gardens. It is a native of Australia, and was introduced to Britain about 16 years ago from the Swan River. It has a height of from 10 to 20 inches; and carries a profusion of flowers, with a blending of white and rose and yellow in their colours; and may be made to bloom from early spring till November. A variety of it has semidouble flowers.

RHODIOLA. A small genus of ornamental, hardy, perennial-rooted, herbaceous plants, of the crassulaceous order. The mountain species, *R. rosea*, grows wild in the fissures of mountain rocks and of sea-cliffs in various parts of Britain. Its root is thick and somewhat fleshy, and much divided at the crown; its herbage is smooth, glaucous, succulent, and about 8 inches high; and its flowers are numerous, and have a cymous arrangement, and are yellow in colour with bluish anthers, and bloom from May till July. The root, when recently dried, emits a fragrance similar to that of rose-water; and it thence gives the whole plant the popular name of rose-root.—The Siberian species, *R. sibirica*, was introduced about 20 years ago, and is smaller than our native species.

RHODODENDRON. A genus of ornamental, exotic, chiefly evergreen shrubs, of the rhodora tribe. Nearly 30 species, varying in height from a few inches to about 30 feet, have been introduced to Britain; and a countless number of most magnificent hybrids have been raised by British cultivators. The genus is one of the most splendidly floral of all the ligneous ones in the world; and now rivals the rose genus itself, in both prominence of position and brilliance of effect, in British shrubberies and gardens.

The yellow-flowered or officinal rhododendron, *R. chrysanthum*, is a native of the mountainous parts of Siberia, and was introduced to Britain in 1796. It is one of the smallest of the rhododendrons, and has commonly a height of only between 5 and 10 inches. Its branches are spreading; its bark is brown; its leaves are few, terminal, oblong-ovate, smooth, and stiff, and are rugged and deep green above and ferruginous or glaucous below; its flowers grow in umbels at the ends of the branches, and are large and yellow, and have a monopetalous, five-segmented, outspread corolla, and bloom in June and July; and its capsules are ovate and somewhat angular, and contain numerous, grey, irregular, small, sawdust-like seeds. The leaves of this plant are used in medicine; and have an austere, astringent, bitterish taste; and contain tannin, green wax, and various extractives; and yield their virtues to water by either infusion or decoction; and act upon the animal system stimulatingly, narcotically, and diaphoretically; and are administered to both men and cattle in cases of very bad or obstinate rheumatism; but, when taken in over-dose, produce vomiting, purging, intoxication and delirium.

The rusty-leaved rhododendron, *R. ferrugineum*, is a native of the Alps, Apennines, and other mountains of Continental Europe, and was introduced to Britain about the middle of the last century. It has commonly a height of from 1½ to 3 feet. Its branches are numerous and irregular; its bark has a dark brown colour, tinged with purple; its leaves grow numerously on every twig, and occur in a pleasingly irregular order, and have a lanceolated outline, reflexed edges, and smooth surfaces, and are beautifully green above, and of an iron colour below, and little more than an inch in length; and its flowers come out in round bunches at the ends of the branches, and have funnel-shaped, rose-coloured petals, and bloom from May till July. A variety of this species is more dwarfish than the normal plant, and has white flowers.

The hairy-leaved rhododendron, *R. hirsutum*, is a native of the mountains of Switzerland and Austria, and was introduced to Britain about the middle of the 17th century. It has commonly a height of from 15 to 30 inches. Its branches

are numerous, and have a lightish brown bark; its leaves are plentiful, irregular, and sessile, and have an ovate-lanceolate outline, and are clothed on their edges and under-surface with ferruginous hairs; and its flowers are similar in inflorescence and form to those of the preceding species, and have a light red or scarlet colour, and make a showy appearance, and bloom from May till July. A variety of it has variegated leaves.

The Daurian rhododendron, *R. dauricum*, is a native of Siberia and Chinese Tartary, and was introduced to Britain in 1780. It grows in such profusion and so densely in many of the pine forests of the subalpine districts of central Asia as to make whole tracts appear one sheet of blossom. It differs from almost all the other species, both in being deciduous, and in blooming at an early period in spring. It has commonly a height of about 3 or 4 feet, and is cultivated both in the greenhouse and in the open ground. Its branches are numerous, and have a brown bark; its leaves come out without order on short footstalks, and are broad, naked, smooth, and comparatively small; and its flowers are wheel-shaped and large, and have a beautiful rose colour, and bloom from February or March till May. Its leaves are sometimes used as a substitute for the leaves of the tea-plants. One variety of it has pale green leaves, eventually changing to a brownish tint; and another has dark green or sooty green leaves and purple flowers.

The largest rhododendron, or American mountain laurel, *R. maximum*, is a native of Virginia, and was introduced to Britain in 1736. It has commonly a height of from 6 to 24 feet. Its branches are few and irregular; its leaves come out irregularly on short footstalks, and are large, ovate-lanceolate, and acutely reflexed, and have a shining strong green colour, and present some resemblance to the leaves of the common laurel; its flower-buds form at the ends of the branches, and begin to swell early in autumn, and look turgid and imposing throughout the winter; and its flowers come out in roundish bunches, and are very showy and splendid, and have a pale blush colour within and a peach colour without, and gradually fade away through a series of whitening tints, as they grow old, and bloom from June till August. One variety of it has white flowers; and another variety, or a hybrid, has white and purple flowers.

The Pontic rhododendron, *R. ponticum*, is a native of the East, and of moist shady places near Gibraltar, and was introduced to Britain in 1763. It has commonly a height of from 4 to 15 feet. Its branches deflect without order from the sides of the stem; its leaves stand on short footstalks, and are spear-shaped, acute, and glossy on both surfaces; and its flowers come out in clusters from the ends of the branches, and are bell-shaped and of a fine purple colour, and bloom from May till July. The varieties of this species, which occur in gardens and nurseries, are very numerous,—a few of them imported from Gibraltar, Armenia, and Nepaul, but most raised from seeds or by hybridizement in Britain; and some of the oldest or most remarkable are the white-flowered, the blue-flowered, the rose-flowered, the twisted-petalled, the rubescent, the great-flowered, the double-flowered, the obtuse-leaved, the narrow-leaved, the ovate-leaved, the long-leaved, the silver-leaved, the golden-leaved, the marginate-leaved, the myrtle-leaved, the willow-leaved, the cassine-leaved, the kalmia-leaved, the showy, the beautiful, the azalea-like, and the intermediate.

Some of the most brilliant of the other species are *R. catawbiense*, introduced from North America in 1809, from 3 to 6 feet high, carrying purple flowers from June till August, and comprising varieties of very different colours; *R. arboreum*, introduced from Nepaul in 1820, from 6 to 25 feet high, carrying scarlet flowers in April and May, and comprising many varieties of widely different colours; *R. punctatum*, introduced from North America in 1786, from 3 to 8 feet high, carrying pink flowers from June till August, and chiefly distinguished by its dotted leaves; *R. caucasicum*, introduced from Caucasus in 1803, from 1 to 3 feet high, carrying purple flowers in August, and comprising varieties with rose-coloured, deep red, and straw-coloured flowers; *R. catesbœi*, introduced from North America in 1810, from 3 to 6 feet high, carrying purple flowers in May and June, and comprising red and rosy flowered varieties; and *R. Farrerœ*, introduced from China in 1829, about 3 or 4 feet high, and carrying lilac flowers in February and March. The hybrids which cannot properly be referred to any one species are almost numberless, and, in many instances, rival or excel the finest normal plants or natural varieties in beauty and brilliance.

The rhododendron is often planted among collections of American shrubs, or what are called American gardens, as if it were exclusively or characteristically American; but it figures well and rightfully on all sorts of dressed grounds, and in all kinds of choice shrubberies, and is alike suited to the front of a border, to the expanse of a lawn, to the side of a walk, to unique groups, and to mixed clumps. It prefers a soil of sandy peat, but will thrive amid either a preponderance of sand or an excess of mould. Its power of pleasing resides in the combined effect of habit, foliage, and bloom,—and is so great in the first and the second, irrespectively of the third, as to render it everywhere mighty and beautiful as a mere evergreen; yet both its chief diversity within itself, and its main fascinations during the period of bloom, exist in the varied colours and tints and forms and aggregations of its gorgeous flowers. "The narrow and rather mean-looking leaves of some of the ordinary varieties look poor by the side of the Catawbiense, which is oval and

shining, and of some of the hybrids, which are of considerable size. However, the foliage, though rich among the good sorts, and very noble on well grown, close, bushy, or finely headed plants, is not of much importance among the common varieties. In an ordinary shrubbery many people would seek to plant some of the earliest, and many of the hybrid varieties are as early as March and April; but the disadvantage of these early ones is, the flowers being spoiled by the spring frosts, which is almost always the case; so that, for choice in planting, we should take those which do not bloom before June or the end of May. Nothing is more vexing than to see a perfectly hardy and handsome plant throwing out its still more handsome blooms, and a frost hardly hard enough to whiten the grass of a field, in one night destroying all the flowers that are out. The only diversity worth mentioning among the leaves of the rhododendron is, in the two variegated kinds,—one the gold-edged, the other the silver-edged; these look very well in a border or clump, but the flowers are mean. The best and handsomest of the ordinary kinds are the varieties of *R. catawbiense*, for the foliage is good, the habit fine and close, the flowers varied from white, or nearly so, to dark rose and dark purple, and all the grades between them." Yet almost equal to these for general purposes of decoration, and quite superior to them for particular purposes or in particular situations, are *R. alta-clerense*, a magnificent, crimson-flowered hybrid of 15 feet in height, produced in 1827,—many of the other hybrids which cannot be assigned to species,—and some of the most select varieties of *R. maximum*, *R. arboreum*, and *R. ponticum*.

RHODORA. An ornamental, deciduous, hardy, calyciflorous shrub, of the heath order. It constitutes a genus of itself, and is specifically called *canadense* or the Canadian; yet it forms the type of a large and most imposing tribe, comprising the rhododendrons, the azaleas, the kalmias, the ledums, and five other genera. It is a native of Canada, and was introduced to Britain about 80 years ago. It has commonly a height of about 3 or 4 feet; and it carries purple flowers in April and May.

RHUBARB,—botanically *Rheum*. A genus of hardy, exotic, tap-rooted, medicinal, and culinary plants, of the polygonum family. About 15 species have been introduced to Britain from western and south-western and central and eastern Asia, and from Austria and Bucharia and European Turkey; and they vary in height from 2 or 3 to 10 feet, and, for the most part, carry white or whitish-green flowers in May and June. Five or six are cultivated for sake of the medicinal properties of their roots; and most of these, as well as all the rest, have acidulous, esculent stems, which are used for tarts or in some other and similar culinary way. But the best medicinal roots are obtained from the three species, *R. palmatum*, a native of Bucharia, introduced to Britain in 1763,—*R. undulatum*, a native of China, introduced to Britain in 1734,—and *R. australe*, a native of Nepaul, introduced to Britain in 1823; and the best esculent stems, or rather the only ones which the present state of British horticulture will admit to be tolerable, are produced by British hybrids of comparatively recent origin.

The rhapontic rhubarb, *Rheum rhaponticum*, was introduced to Britain about 127 years before any other species, and became so early and generally diffused, and at the same time became so permanently predominant as to take the name of English rhubarb. A brief notice of this species will convey a sufficient idea of the general appearance of the whole genus. It is a native of the parts of Asia which border on the Black Sea. The root is large and thick, and sends down many subdivisions deep into the ground, and is interiorly yellow and exteriorly of a reddish brown colour. Several leaves, varying in number according to the size and strength of the root, come up foldedly from the root-crown in spring, and afterwards expand themselves; they are smooth, and roundish heart-shaped, and a little waved on their edges, and have a deep green colour, and are traversed from the footstalks to the borders by several strong longitudinal veins, and, on good soil, are often two feet in diameter. The footstalks have a reddish colour, and are a little channelled on their lower side, but flat at the top, and, on strong or even middle-rate plants, are nearly two feet long and thicker than a man's thumb. The flower-stem rises from among the leaves, and has a purple colour, and is garnished at each joint with one sessile leaf, of the same shape as the radical leaves, but comparatively small. The flowers form a thick, close, obtuse spike at the top of the flower-stem, and have a white or greenish white colour, and bloom in May and June, and are succeeded by large triangular brown seeds, which have a border or wing at each angle, and ripen in August.

The red Goliah rhubarb is one of the best of the hybrids for culinary purposes, and as superior to the old harsh, dock-like rhubarbs which were generally prevalent even 10 or 11 years ago as our cultivated celery is superior to the rank weed of the same name which grows by muddy ditches. It is as easily propagated as any other perennial vegetable; and so hardy as to resist the frosts and vicissitudes of our severest seasons; and of all esculents for pies and tarts and puddings, it is the most easily prepared. It is so prolific, too, that half a dozen roots would keep a small family constantly supplied, during 4 months of the year, that is, from the beginning or middle of April, according to the forwardness or backwardness of the season, until the beginning or middle of August; and it is sometimes preferred to all other vegetable substances for the purpose

of pastry, throughout the summer, even where fruits of every kind abound. Stalks of the red Goliah rhubarb have been known to measure 6 inches in circumference and nearly 2 feet in length, so that only one of them was required for a pudding. So delicate and soft, too, is its texture, that as soon as it arrives at the boiling point, it becomes a fine pulp, and is already sufficiently cooked. As a garden production for culinary purposes, it is certainly of much value; being in perfection precisely at that season when apples become tough and scarce, and before gooseberries have made their appearance. Its flavour is so delicate, that it ought not to be mixed with any other ingredient than sugar; and on no account should it ever be peeled. The eyes or buds of the red Goliah rhubarb have a deep rich red colour; its leaves are of different hues of green; and its stalks have a green ground colour, spotted and streaked with red. Its leaves are of enormous size,—sometimes 4 feet long and 3½ wide; its roots also are gigantic,—so large that, in the course of 3 or 4 years, a single root, when dug up, would fill a wheel-barrow; hence, the plants require a wide space,—say 5 feet every way, or 5 feet by 6. Either this hybrid or any other kind of culinary rhubarb may be propagated from seeds, or from young roots of one year's growth, or from clean offsets with each two or three bold eyes. The soil should be rich, and may be prepared in the same way as for asparagus beds. Seeds may be sown either somewhat thickly, with the view of the plantlets being transplanted in a few weeks, or at wide distances and in regular rows, with the view of the plantlets being merely thinned out and allowed to remain permanently when raised. The sowing may be done in September or October, and the final thinning toward the close of the following summer; and intermediate cleanings and hoeings must be given in spring. Roots or offsets may be planted in March, in dry weather, in an open state of the ground, and during a temperate state of the atmosphere. Plants from vigorous roots may be available for use so early as 4 or 6 weeks after planting; but, generally, plants from offsets ought not to lose a stalk or a leaf, except by natural decay, till the following year. When the growth of transplanted rhubarbs or of plants from offsets becomes established, the ground must be kept free from weeds; and if dry weather supervene, water ought to be given freely around the roots two or three times, at intervals of 4 or 5 days. In ordinary culture, nothing farther is done, except to manure the bed in autumn after the leaves have decayed,—and even the waterings in a time of drought are not attended to; but in more refined culture, some special methods are used for promoting luxuriance, succulency, flavour, and blanching. In autumn, the decayed leaves are laid in little trenches, formed along the centre of the spaces between the rows, sprinkled with a handful or two of salt, and covered with the earth that had been dug out; as the winter approaches, a coating of well-decomposed stable-manure or leaves, or a mixture of both, two or three inches deep, is laid round each plant to the extent of two feet; and in the open weather of February, or before the new growth appears, the whole bed is forked over, and a mimic mound, of drift sand, or of light porous earth, or of the soil in the central space between the rows, is formed to the thickness of a foot over each plant, —and this mound must be removed as soon as the season of pulling or of cutting ceases. When the red Goliah is gathered for use, the stalks should never be cut from the bed, but wrenched sideways with a sudden twist, and they will then come away entire from their junction with the root,—round, flat, clear, and as white as milk. As soon as the growth of rhubarbs of two or at most three years old becomes vigorous, the flower-stem begins to ascend from the root-crown of each plant; and this will readily be distinguished from a leaf-stalk, and ought instantly to be pulled away, except from some one plant which is intended to produce seed; and this plant should be less gathered from than others, or not gathered from at all, during the season,— and must not by any means be subjected to the blanching or mound-covering method in spring. The seed should be gathered as soon as ripe; and care must be used that none of it be scattered over the beds; for young plantlets from it might grow up unobserved among the old plants, and greatly rob them of their spreading-room and nourishment.

The foreign rhubarb root of the drug-shops is of two qualities,—the one from Russia and Turkey, containing an excess of tannin, resin, and oxalate of lime,—the other from India or China, containing an excess of extractive matters and gallic acid,—and both, in addition to these principles, containing mucus, alumina, silica, gum, starch, lignin, albumen, and a colouring matter. Good Russian or Turkey rhubarb has a peculiar sub-aromatic odour, and a bitter sub-acid, slightly astringent taste, and breaks with a rough fracture, and is easily pulverized, and affords a bright buff-yellow powder; and Indian or Chinese rhubarb has a stronger odour and more disagreeable taste, and breaks with a smoother fracture, and affords a darker-coloured or more reddish powder. British rhubarb root, also, has been extensively brought into the drug market, and may be grown on any very rich soil of medium texture, and taken up in the third or the fourth year from the time of sowing, and cut into pretty large pieces, and dried either in the sun or in specially constructed kilns; yet it is generally found to be much inferior in quality to the foreign and imported rhubarb root; and it is supposed to owe its inferiority mainly or even entirely to the manner of drying it. "In Tartary," we are told, "the roots are taken up

twice a-year, in spring and in autumn; and after being cleansed and decorticated, and the smaller branches cut off, the body of the root is divided transversely into pieces of a moderate size, which are placed on tables, and turned 3 or 4 times a-day during 5 or 6 days. A hole is then bored through each piece, by which it is hung up to dry, exposed to the air and wind, but sheltered from the sun. In about two months, the roots have lost seven parts in eight of their weight, and are fit for the market." But a variety of ways has been recommended as most suitable in Britain; and some of the chief of these are discussed in seven articles by different writers in the first volume of the Bath Papers.—Rhubarb root is medicinally used in powder, in infusion, in tincture, in extract, and in various solid and liquid combinations; and it acts on man as a tonic and an aperient, and is useful in dyspepsy, hypochondriasis, and relaxation of the bowels; but, in cattle medicine, it is of small service, and acts only or chiefly as a stomachic. The colouring principle of it is of some service in some of the arts.

RHUS. See Sumach.

RHYNCHOSIA. A diversified genus of exotic plants, of the kidney-bean division of the leguminous order. About 20 species have been introduced to British gardens; two or three of them hardy, but the majority tropical; two or three annuals, and the rest perennials; two or three erect, and the rest climbers or twiners; some ligneous and some herbaceous; two or three with simple leaves, and the rest with trifoliate leaves; three or four with white or brown or purple flowers, and the rest with yellow flowers; four or five ornamental or handsome, and the rest possessing little or no beauty; four or five from 5 to 8 feet high, and the rest from 1½ to about 4½ feet high. Fully one half of the species are assigned by some botanists to the genus glycine, and three or four of the others to the genus dolichos. See the articles Glycine and Dolichos.

RHYNCHOSPORA. A genus of sedgy or coarsely grassy plants, of the cyperaceous order. The name signifies 'beaked seed,' and is descriptive. Two British species, the white-headed and the brown-headed, both about a foot high, and blooming in autumn, occur in bogs; and nearly 40 foreign species are known.

RIBBING. A slim method of half ploughing stubble-land. It consists in throwing up the land, after harvest, into a kind of one-bout ridgelets or drills, leaving a slip of fast soil unploughed between every two drills, and covered up by the two ploughed plots. It is nearly the same thing on stubble land as raftering is on grass land. See the article Raftering. It is practised on all sorts of soils, but chiefly when they are in a very foul state, and are intended next year for barley; but it is condemned, in all circumstances, by the majority of good practical farmers, as slovenly, unfarmer-like, and eventually wasteful; and it has been abandoned in many districts where it once was common, and is now rarely practised in any but remote or backward districts. It is usually done with the small one-horse plough.

A species of drilling in spring, with the small plough, is also called ribbing; and this is sometimes found to be peculiarly suitable on soils of a soft friable texture, and also on clays which have been long ploughed, and on naturally soft soils of any kind which have become so smooth as to seem incapable of affording sufficient cover for the seed in the ordinary way by the harrow. A particular implement, somewhat in the form of the old, heavy, quadrangular grubber, has been recommended for doing this kind of work; but a common grubber can at any time be converted into an efficient and economical ribbing-machine, by changing its common tines for a set carrying each a pair of small mould-boards.

RIBES. A genus of calyciflorous, deciduous shrubs, constituting the natural order Grossulariaceæ. This order is nearly allied to the cacti family, but may readily be distinguished from them by the woodiness and leafiness of its stems and by the definite number of its stamens. Seven species of it grow wild in Britain; upwards of 30 have been introduced from other countries,—principally North America and Continental Europe; and a number more are known. Three of the introduced species are procumbent or trailing plants; and all the other introduced species, as well as all the indigenous ones, are upright shrubs, nearly all hardy, and the great majority from 3 to 6 feet high. One group or subgenus are represented by our common gooseberry plant, and, with one exception, have greenish-white flowers; another group are represented by our common red currant,—and some of these have naturally red fruit and others black fruit; a third group are intermediate between gooseberries and currants, and produce their fruit in bunches somewhat similar to those of grapes; and a fourth group are unarmed shrubs, and have yellow, tubular calyxes and many-flowered racemes. The rough gooseberry, the smooth gooseberry, the red currant, and the black currant, in their many cultivated varieties, are universally known as the most common fruit-shrubs of Britain; several other species produce fruit not greatly inferior to that of the red currant; and the majority of the rest produce tolerable, watery, sweet, acid berries. Many, also, are very ornamental, and some make a prominent figure among the most exquisite beauties of the shrubbery.

The two gooseberry species, the red currant, and the black currant, grow wild in respectively the hedges, the river banks, and the moist hedge-banks of some parts of Britain; and they will be found sufficiently noticed in our articles Gooseberry and Currants. Yet we may remark here

that, among the varieties of the red currant, are to be reckoned the white-berried, the striped-berried, and the flesh-coloured-berried,—that among those of the black currant are to be reckoned the green-berried and the yellow-berried,—and that the berries of the black currant possess tonic and stimulant properties, while the leaves of it are glandular and secrete a rich fragrant aroma, remotely similar to that of tea but very much stronger.—The alpine currant, *Ribes alpinum*, grows wild in the woods of Britain, and has green flowers and an ordinary height of about 3 feet, but comprises both a smaller variety and a larger one,—the latter a garden plant with variegated leaves.—The rock currant, *Ribes petræum*, grows wild on the mountains of some parts of England, and has reddish flowers, and an ordinary height of about 4 feet.—The spiked-flowered currant, *Ribes spicatum*, inhabits the moist woods of some parts of England, and is about as tall as the preceding, and has green flowers.

The flowering currant, or bloody-coloured flowered currant, *Ribes sanguineum*, was introduced to Britain from North America only 22 years ago, and is already an universal beauty of shrubberies, and even a very common one of small cottage plots. It commonly attains a height of about 6 feet, and blooms in April and May, and has naturally deep red or blood-coloured flowers; and it comprises many seedling varieties, differing from one another in the colour of their flowers, from the brightest pink to the bloodiest crimson, and from either of these, through all the lighter shades, up to almost pure white. Four old and principal varieties are *R. s. atro-rubens*, with dark red flowers,—*R. s. malvaceum*, with dark pink flowers,—*R. s. glutinosum*, with pale pink flowers,—and *R. s. alba*, with white flowers. But a double-flowered variety, *R. s. flore-pleno*, which was raised a few years ago in the Earl of Selkirk's garden at Kirkcudbright, greatly excels all the old varieties,—coming three weeks later into bloom, so as to escape the spring frosts, continuing longer in bloom, and, not only having double flowers, but producing them in gorgeous pendulous racemes of from 3 to 6 inches in length. The flowering currant, in all its varieties, is one of the most rapid-growing and unfastidious of garden shrubs, thriving well in any common soil, and readily propagable from either layers or cuttings.

RIBGRASS. See PLANTAIN.

RICE,—botanically *Oryza*. A small genus of exotic, annual, cereal grasses, with a panicled inflorescence similar to that of the millets, the bents, and the canary-grasses. It has six stamens, two styles, two one-flowered glumes, and two persistent and equal paleæ.

Rice is indigenous in many parts of both Asia and Africa; and it is cultivated in all the warmer regions of the Old World, in many of the southern parts of Europe, and in not a few places of North America, but especially Carolina. It was cultivated in the East at periods beyond all record; it was long ago introduced to the countries immediately north of the Mediterranean,—Turkey, Greece, Italy, and Spain; it was more recently introduced to Hungary and Central Europe; and it first found its way into the Western hemisphere about the beginning of the last century. Attempts have been made since 1821 to cultivate it in England, Holland, France, Switzerland, Westphalia, and Central Russia,—and these have been particularly directed to the mountain species of it, which is hardier and has much shorter and more rounded grains than the other kinds, and thrives on dry ground while they thrive only on marshy or irrigated lands; but, for all practical purposes, these attempts have entirely failed in England, and have nowhere sufficiently succeeded on the Continent to warrant the hope of ever raising a produce which shall compete in the market with rice imported from Carolina or Bengal. Yet an account of rice-cultivation in the East must be interesting to British farmers and gardeners, not simply as a matter of curiosity, but for the hints which it suggests toward the improved management of all British field plants which love much heat and moisture.

Mr. Porter's definition of rice, in his Tropical Agriculturist, is at once so succinct and correct, that we cannot do better than quote his words. "Rice," he says, "is an annual plant, rising with a round jointed stalk, similar to that of wheat, but the joints are more numerous; its height varies from one to six feet, according to the variety. The leaves are subulate, linear, and reflex; embracing the stalk—they are not unlike those of the leek. The flowers are in a terminating panicle, and are succeeded by single oblong seeds, borne on separate pedicles, which spring from the main stalk of the panicle or ear. The grains are enveloped in rough yellow husks, and from each proceeds an awn or beard; within the husk is a thin pellicle. The whole of the ear more nearly resembles that of oats than any other of the grain-bearing plants grown in England. These seeds, divested of their husk and pellicle, are the rice of commerce. Before they are husked they are called *Paddy;* or more correctly *Paddie*." It were an endless and a useless task to attempt an enumeration of the varieties of rice in cultivation. Heyne enumerates no less than twenty-three kinds, each having a peculiar name and character, grown in the Mysore alone; and Baboo Radhakant Deb, has recently given twenty different varieties of cultivation in as many different districts. The whole, however, may be classed as varieties only of the four great heads, the *Oryza sativa*, or common rice, which thrives only on marshy soils,—the *Oryza præcox*, which also delights in humid situations,—the mountain rice or *Oryza mutica*, which is cultivated in Cochin China, and in Java, and which has its most congenial situation on the slopes of hills,—and the *Oryza glutinosa* or clammy rice, which is an intermediate variety between the mountain rice and the other two kinds, ripening sooner than some, and later than others, and growing alike on wet and dry soils. The periods of maturation of course depend not only on the subvarieties of the plant, but on the soil and climate, and hence the common rice takes according to circumstances from three to even seven months

before being properly ripened. Four and a-half months may be considered as the average time, and two crops are expected annually. The rice in its wild state sows itself in the early winter months, vegetates during the season of the early rains, ripens during that season, and again drops its seed at the approach of wintry weather.

A level surface is essentially necessary for the cultivation of rice, as frequent inundations must be had recourse to. Where this is not the case, the ground is divided into terraces; and to irrigate these, great pains are taken to conduct the waters of the neighbouring springs and rivulets. When the descent is steep, these terraces are often not more than two or three feet wide. In May the preparation of the rice fields commences; frequent ploughing is had recourse to, where that is practicable; but where it is terraced, only the hand-hoe can be used. Whenever circumstances permit, the ground is previously manured, the produce being thereby rendered not only greater, but of superior quality. The seed is sown in a corner of the field, and the plants remain there, till about a foot high. When the soil has been irrigated sufficiently, so that it can be reduced to mud by the hoe, the time of transplantation begins, and this is generally about the middle of June. The seedlings are then carefully plucked up by the roots and planted out, the field being subsequently laid under three inches of water—which after being allowed to stand for a few days is again drained off, and a fresh inundation resorted to. For accomplishing this transplantation only the finger is used, with which a hole is made, for the reception of the seedling. Vegetation then proceeds rapidly. In Behar such is the prodigal richness of nature, that in two months from planting the rice is ready for the sickle. In August a second crop succeeds, and is reaped in November. "Planting a rice field," says Mr. Porter, "is in India a period of jollity and bustle, and the usually inactive Hindoo then displays an alertness and vivacity, which for a while overcomes the phlegmatic indolence of the race." Mr. Tennant in his Indian Recreations, bears also concurrent testimony to the same fact. "This is the grand season of business," he observes, "with the Hindoo farmer, when his concerns absorb those of every other man in the community. He has then a prescriptive right, established by the practice and usage of some thousand years, to call out not only the artists of the village, but their women and children, to his assistance; though the hurry of business should continue a week or two."

To facilitate the practice of irrigation, so essentially necessary to the successful cultivation of the common rice, the neighbourhood of streams and rivers is generally selected. The only other resources are the construction of artificial tanks, or the drawing of water from wells, a process of great labour. In his Agricultural Survey of Bagulkot and Badamy, Dr. Marshall observes, that the culture of rice from a tank or reservoir is so distinct a process as to call for a separate description. "There are," he says, "three of these tanks in this district, the principal is in the vale of Kendow near Badamy, and occupies about 500 or 600 acres. It maintained its depth of from three to six feet nearly at all seasons, being supplied by perennial springs from the hills which surround it, and nothing short of an absolute failure of rain dries them up. It is closed at its southern end by a mound, but the water is perpetually flowing by three or four channels communicating with its bottom by springs, and what thus escapes is sufficient to inundate a tract of about two miles in length, and one in breadth, which is entirely devoted to the rice culture. The fields are not terraced, but appear to be all on one level; there must, however, be an imperceptible slope, as the water does not ever seem to be absolutely stagnant, but there is always a flow from the tank to the river below. The land is perpetually a plunge of two or three feet deep of mud; in this state it is worked, sown, and weeded, and in this state is the grain reaped. Each man's field is separated from his neighbour's, by an embankment of scarcely more than six inches high, and is divided into a number of little rectangles of four or five yards long, and two or three broad, the banks of which are three or four inches high. Two crops are obtained annually, one sown in August, the other in February; the latter is reckoned considerably the best, as in the other the ripening grain is exposed to cold weather, which is injurious to its filling. The ground has not more than fifteen days respite between the reaping of one crop and the preparation for the next." Where streams are not present, and where tanks are not used, the water for irrigation is sometimes laboriously drawn from wells, by the aid of bullocks, in a manner peculiar to India. In a steep acclivity from the edge of the well, a path is made just sufficient for two bullocks to walk abreast, and this walk is proportioned in length to the depth of the well. A wheel or pulley is placed over the well, fixed to substantial beams of wood; and over the wheel or pulley is placed a rope attached to an iron or leathern bucket, ending at bottom in a conical flexible point. To this another rope is attached and conducted over another pulley, placed considerably below the other. The extremities of both of these ropes being fastened to the bullocks, and the animals made to move in a retrograde direction towards the well, the bucket necessarily descends, and fills itself with water; when they are driven forward again, the bucket of course again ascends to the top. The second rope fastened to the flexible extremity of the bucket, being the shorter of the two, it gradually in ascending becomes tightened, and on reaching the height of the channel, where the water is intended to be discharged, it is thrown over and empties itself. Mr. Hamilton in his statistical survey informs us, that if the bullocks are well broken in, one man is capable of managing the whole, and that an eighth of a ton may be raised at once by this simple, yet curious plan.

The mountain rice is much less expensive in its cultivation, as it requires neither such outlay in preparation of soil nor labour in irrigation. In March the land is well hoed and manured, and this operation is for three or four times repeated weekly, and the clods pulverized by a mallet. After the showers of May, it is again hoed, and the mould still farther broken down and smoothed over. Drills at a span's distance are then made by the finger, directed by a line, four or five seeds being deposited in every span's length. A small sprinkling of mould is then laid over them. In four or five days the young plants make their appearance, and from the middle of June to the middle of August, the weeding of the ground by means of a spade becomes frequently a very necessary operation. In the moister grounds, especially those of Nepaul, when the plants are about two feet high, the ground comes to be infested with slugs, worms, and other vermin,—to destroy which, the farmers turn a number of ducks into the rice-grounds. In the earlier part of September the crop usually ripens, and the harvest is gathered in by the middle of the same month. This is done simply by cutting off the ears, which have the grain beat out of them the day after they are reaped, and thereafter it is dried in the sun.

The cultivation of rice is considered, under most circumstances, to be a very profitable speculation. The rice-crop of Bengal is considered to be generally better than that of any other part of India, and is estimated at 40 bushels per acre. Hamilton estimates the average of Nepaul at only 28 bushels. We

are told by Crawfurd, that in Java an English acre of good land yields annually, besides a green crop, 641 lbs. avoirdupois of clean-grained rice; but, on the lighter soils, where two crops are reaped annually, an acre does not average above 285 lbs. per crop. Even in the rich plains of Lombardy, the average crop per acre is only estimated at 48 bushels per acre; and in the Carnatic, where four crops are raised in one year, two on the same ground, we are told by Mr. Porter, that the first crop produces fifty-fold, the second forty-fold, the third the same, and the fourth between twenty and thirty fold. Rice in Java yields, under favourable circumstances, from twenty-five to thirty-fold; but the produce of the mountain-rice does not exceed half this quantity.

The separation of the grain from the ear is, in most countries where rice is extensively cultivated, performed by means of a hand-flail; no machine having yet been contrived for the successful performance of this operation. As the husk adheres very tenaciously, it is passed through a pair of millstones, so far separated from each other as to remove the husk without crushing the grain; the pellicle being afterwards disengaged by trituration in large mortars. The rice of India is for home-consumption husked dry; but when intended for exportation, it is scalded. Paddy or rice in the husk is now imported into England, in considerable quantities, and a great saving of price is thus made. Not only is there less waste in the transportation, but it is divested of the husk much better by the improved machinery of England than by the rude and simple Indian method. The apparatus for this purpose was invented by Messrs. Lucas and Ewbank, who obtained a patent for its exclusive use in the year 1827.

RICHARDIA. See CALLA.

RICINUS. See PALMA-CHRISTI and CASTOR-OIL.

RICK. A pile of corn, hay, straw, or other field produce, regularly heaped up in the open air, and sheltered by thatch from rain and snow. See the articles STACK, HAYMAKING, and BARN-MANAGEMENT.

RICK-CLOTH. See HAYMAKING.

RICK-YARD. The department of the farm-yard appropriated to ricks and stacks.

RIDDER. An addition made to some varieties of the Scotch swing plough, for clearing away the stubble from the coulter. It is a very simple contrivance; but is not needed in any of the thoroughly good constructions of the plough. See the article PLOUGH.

RIDDLE. A sieve, with a circular rim of wood and a bottom of open mesh-work, for separating large and heavy impurities from grain. It may have either a wire or a wooden bottom; and it is made of different diameters, and with different widths of mesh, to suit different purposes and different grains. See the articles SIEVE and BARN-MANAGEMENT.

RIDGE. The portion of a ploughed field intermediate between two open furrows.

The disposing of fields in ridges is designed to facilitate surface drainage; and may be regarded as indispensable on all retentive soils in a wet climate. But wherever it is not really required for sufficient drainage—as on all lands which are suitable for the action of the turnwrest plough, and on all which are naturally porous enough, or artificially subsoil-drained enough, to effect the rapid absorption and permeation of excess of moisture from prolonged and heavy rains—it must be pronounced exceedingly wasteful and injurious,—occasioning as much loss of land as the furrows occupy, as much loss of soil and manure as the surface-drainage sweeps away, and as much deficiency of crop as arises from unequal distribution of moisture. See the articles DRAINING and PLOUGHING. The very high ridges of some parts of England, too, and the very narrow ones of some parts or even most parts of Ireland, entail some serious additional disadvantages of their own. "In highly elevated ridges," remarks Martin Doyle, "the mould is accumulated to such a depth in the centre that it becomes inert, while the soil on the sides approaching the furrows is gradually more shallow; a very high ridge is also under the inconvenience of having the sunny side more luxuriant, and sooner ripe, than the other side less favoured by the sun, or more exposed to wind. The common Irish, like the Norman farmer, who has often a winding ridge (but only because the side of the field at which he commences happens to be crooked), and always an extremely narrow one, four feet, cannot assign any good reason for his bad practice, when on perfectly dry land, except that from habit he would not know how to plough if he had not his frequent furrows to direct him." Ploughing without any kind of ridges, too, or with a perfectly flat and uniform surface, effects a considerable saving of the labours of tillage, and puts the ground into the most convenient state for the operation of mowing, and is favourable for the conversion of arable land into grass. The best methods of it are with the turnwrest plough,—and in broad level ridges with the common plough, followed by a one-bout filling of the inter-furrow,—and in concentric lines round and round a hill from the circumference to the centre, or from the centre to the circumference. "This mode," remarks Sir John Sinclair, in reference to the last of these methods, "requires little more force than common ploughing; it is likewise an expeditious mode, as there is no occasion for turning, and is economical, as by it every inch of the soil is moved."

Whenever ridges are necessary, they ought to be perfectly straight, and to have such a length, breadth, and direction as will best promote economy and best suit the conditions of the land. A length of about 150 yards is very suitable on fields with much acclivity,—of from 240 to 300 yards on wet soils,—and of from 350 to 400 yards on somewhat dry soils. The proper breadth is a subject of great debate among farmers of different views and different districts; but ought to be as great as will comport with thorough drainage and general convenience, and must, in some degree, be determined by character of soil and climate, and by the mode of culture, whether

drill or broadcast. The direction on any field which has an uniform surface and nearly a dead level, ought simply to coincide with the natural water-fall; but the direction on a decidedly sloping field, and still more on a very uneven or very declivitous one, requires consideration, and must be different in different circumstances, and ought, in every practicable or convenient case, or in all other cases as nearly as possible, to be eastward and westward so as to expose both sides and all parts of every ridge equally to the weather. When ridges are planned on the same level along a sloping field, the working of the plough is awkward, and the surface water is liable to be detained in the furrows; when they are formed straight up and down, the uphill working of the plough is difficult to both the ploughman and the team, and the surface water prodigally washes away soil and manure; when they are formed slopingly to the left from the top of the declivity, the uphill working of the plough is about as difficult as in the preceding case, or sometimes more so; and only when they are formed slopingly to the right from the top of the declivity, are the joint conditions of economy and drainage well fulfilled. "When the ridges are laid in this last manner, the horses have a better footing, and the ground always falls from the plough as it goes upward, without any great exertions on the part of the ploughman or the cattle. By this plan, no part of the soil is forcibly turned against the acclivity; but it is so contrived that, on returning down the hill, the furrows fall freely from the plough, and thus every inch of the soil is perfectly turned over. These diagonal ridges are likewise extremely favourable to the cartages of both produce and manure. If there be soil enough, any ground, however steep, may be cultivated on this principle; and by this mode land may be ploughed which would otherwise be impracticable." See the article PLOUGHING.

RIDGELET. A small ridge.

RIDING. See MANEGE.

RID-PLOUGH. A self-cleaning plough. See the article PLOUGH.

RIGIDELLA. A recently discovered genus of ornamental exotic plants, of the iris order. The flame-coloured species, *R. flammea*, was introduced to Britain about 10 years ago from Mexico. It is a very showy and remarkably interesting plant; and has a similar habit, and requires similar treatment, to the old magnificent *Tigridia pavonia*. Its blossoms are beautiful, and have vivid colours, and both develope and fade with astonishing rapidity; their perianth or coloured portion is curiously convolute at the base, and has contractile nerves, and, after being a short time open, rolls itself up in the manner of a screw; the anthers have a prettily diversified hue; and the flower-stalk is partially pendulous or bent while the blossoms are expanded, but rises into a stiffly erect position as soon as the blossoms fall, and maintains that position till the seeds are matured. This plant may be easily grown in a pot of loamy soil, mixed with a little heath-mould and sand; and the bulbs should be taken up when the leaves have decayed, and be repotted toward the month of November. The heat of a greenhouse or of a cold frame is sufficient.

RIME. See HOAR-FROST.

RINGBONE. A bony excrescence around the pastern-joint of the horse's foot. It is caused by concussion; and is formed by the deposition of bony matter in the room of cartilage or ligament. It exhibits every degree from mere incipient deposition up to total anchylosis; and in its approach to the latter stage, it obliterates the joint, occasions permanent lameness, and becomes incurable. The remedy for it in the earlier stages, is a smart and rapid series of counter-irritation, — comprising sweating blisters and setons, and, in bad cases, the actual cautery.

RING-DOVE. See PIGEON.

RING (FAIRY). See FAIRY RING.

RING-FENCE. A boundary enclosure between two farms. See the articles ENCLOSURE and FENCE.

RIPENESS. The maturation of vegetable growth. It means either the natural maturedness of the seeds or fruits of all sorts of plants, herbaceous and ligneous, annual and perennial,— or the sufficient maturedness of any parts of plants, whether seeds, offsets, tubers, cuttings, or whatever else, for the purposes of reproduction,—or the proper maturedness of agricultural and culinary plants, or parts of plants, whether seeds, stems, herbage, or entire bulk, for the most productive or economical harvesting. Remarks on seeds will be found in the articles SEEDS and AGRICULTURAL SEEDS,—on tubers and bulbs, in the articles POTATO and BULB,—and on cuttings, in the articles CUTTING and ABSORPTION IN PLANTS; and remarks on the indications of ripeness will be found in the respective articles on all the principal field and garden crops,—and particularly in the articles on those whose stage of most economical maturity is extensively misunderstood, such as HAY, FLAX, WHEAT, and POTATO.

The uppermost grain in every ear of a cereal crop, and the undermost pod on every stem of a leguminous, is generally the first ripe; so that, in attempting to ascertain the ripeness of growing seeds, the topmost ones of corn crops and the lowermost ones of pulse crops must be examined. In all early and average seasons, the whole ear of a corn-plant is ripe before the straw; and in some late seasons, the straw is ripe, or at least appears to be so, before the ear. Cereal crops, in general, should be reaped before they are quite ripe, or as nearly as possible at the intermediate point between the stage at which they would shrivel from excessive under-ripeness and that at which they would become chaffy in the grain, or liable to lose their seeds, from too complete

ripeness. Oats is the safest cereal crop for cutting before it becomes properly ripe; and barley is the safest for allowing to stand till it becomes fully ripe. "It is difficult," says a writer in the Q. Journal of Agriculture, "exactly to state the ripeness in which corn should be reaped to avoid the shaking out of grains. As a general rule for practice, it may be recommended to reap the culmiferous crops before the uppermost grain can be shaken out either by the wind or in the act of reaping. When that period arrives must be learned by the state of the straw. It is impossible to derive this knowledge from any written description; it must be acquired in the field from personal observation, and afterwards confirmed by experience. If attention is directed to the acquisition of this experience, it will be acquired as easily as the experience which at present directs us to forbear to reap till a certain prefixed day."

In an Essay, in the Transactions of the Highland Society, on the influence of frost and other varieties of bad weather on the ripening of corn, the late Benjamin Bell, Esq., states, on conclusions from a number of experiments, that barley and oats may suffer much and varied buffeting from the weather in every period of their growth without being destroyed, and will even continue to acquire additional weight though frequently exposed to severe degrees of cold, and even occasionally to frost,—that, in late harvests, unripe corns should not be too hastily cut, from an apprehension of their being killed with frost,—that corns will bear a great deal of dry frost, and yet continue to fill, but are less able to resist the effects of rain and wet snow,—that grain which has partially filled or gone on ripening after frost is very unfit to be used for seed, and, if sown, will either not germinate at all, or produce a weak, meagre, and inferior crop,—that beans, pease, and tares are much more liable to be injured by frost than oats, barley, and wheat,—and that all the herbage plants usually sown in Britain are likewise liable to be injured by frost, and none of them more so than the red or broad-leaved clover.

RIPIDIUM. A small genus of exotic grasses, of the villiflorous tribe. Two hardy, perennial species, both about 2 feet high, and blooming in July and August, have been introduced to Britain from Continental Europe. But they are referred by some botanists to the sugar-cane genus, and by others to the genus andropogon.

RIPPLING. See Flax.

RIVER-FARMER. A person who rents a fresh-water fishery for the sake of its fish.

RIVER-MEADOW. An alluvial meadow, or one of low and level surface lying in the bottom of a valley and along the side of a stream. See the articles Meadow, Alluvium, and Irrigation.

RIVINA. A genus of ornamental, evergreen, tropical shrubs and undershrubs, of the goosefoot family. The dyeing species, *R. tinctoria*, was introduced to Britain about 18 years ago from Caraccas. It has a height of 4 or 5 feet, and carries white flowers in May, and is useful in dyeing, and has been called the rouge plant. Six or seven other species, from 2 to 4 feet high, and chiefly with white or with pink flowers, have been introduced from the West Indies and Brazil.

ROACH,—scientifically *Leuciscus Rutilus*. A British fresh-water fish, of the carp family. It inhabits many of our deep, still rivers, and is gregarious, and breeds profusely in lakes, ponds, and weirs. It has a small head, a round, small leather mouth, and large eyes with a gold circle and red iris. It is deep but thin, and has an elevated back. The scales are large, and easily fall off; the fins are in general red, particularly whilst in perfection; the side line bends much on the middle towards the belly; and the tail is a little forked. The roach is so silly a fish that it has acquired the name of the water sheep, in contradistinction to the carp, who for his subtlety is termed the water fox. The flesh of the roach is very wholesome; and the roe, which is green and boils red, is peculiarly good. This fish spawns in May; and is in prime condition in February and March, and in tolerable condition in the latter part of autumn and through the winter, and is caught with baits of gentles, worms, and pastes.

ROACH-BACKED. See Back.

ROAD. A certain portion of land set apart for the purpose of communication between one place and another. As a right line is the shortest that can be drawn between one point and another, so, of course, all roads should be made as straight as local circumstances will permit, in order that we may move from one place to another, by travelling over the least possible portion of space.

For the advantage of general conveyance, roads should be kept as level as possible; because, notwithstanding that facility is afforded to the conveyance of a load down a hill or slope, still as burthens have to be moved in both directions, the ascent of that same hill will occasion a counteracting inconvenience. These may appear to balance each other, and, as far as animal labour is concerned, they probably do so; but in a civilized and commercial country, time is an element that must always be admitted into the calculation, and it is found that the same space can be passed over in less time upon a level road than upon an uneven and hilly one, consequently the level road must have the preference.

Roads should be as hard as possible, in order that they may not wear into holes or inequalities, because a smooth surface is indispensable to their perfection, consequently if the natural soil over which a road passes is not of a proper quality, it will become necessary to obtain and transport hard materials to place upon it. But the great point to be attended to in the formation and preservation of roads is effective drainage. If water is permitted to remain upon a

road, or even in its ruts, hollows, and inequalities, the best materials will fail, and will be incapable of withstanding a heavy traffic; while very indifferent materials may form a tolerably good road, provided proper precautions are used for keeping them dry. A road should also be kept free from all impediments, such as mounds of earth, trees that may be blown down, large stones, or deep pits; because every road should be kept in such a state that it may be travelled over in the darkest night with as much confidence as in broad day-light. To insure all these objects requires a certain degree of care and watchfulness, and frequently a considerable expenditure of money, and the manner in which these objects may be provided for, will be first considered. Roads are usually divided into three distinct classes, called private roads, public or parish roads, and turnpike roads. Public or parish roads, and turnpike or high-roads, are, in some countries, national or government roads.

Private roads are such as are constructed by private individuals, upon their own estates or farms. In these the soil belongs to the proprietor, and he is alone at the expense of constructing and repairing the roads. He may therefore fix gates and lock them up, or change their direction, or destroy and plough them up whenever he pleases, and the public cannot complain; nor indeed have they any right to use them, except by sufferance. In England, it is necessary to lock up such roads occasionally, and to deny passage through them except by permission, and to keep records of such stoppage; because, if a private road is left open to the public for sixty years, it becomes public property, and the proprietor cannot afterwards close it or even change its direction, especially if it leads to a place of public worship.

Public, or *parish roads*, run through a larger district of country, and generally make communications between one farm and another, or between villages and even large towns, so that these roads are much more extensively used; but, inasmuch as they are seldom in the directions that lead directly through a country, they are not so much used by the general traveller as by those who live in their immediate neighbourhood. Such roads are open to the use of the public generally, without any toll or charge; but as funds are necessary for keeping them in repair, and as they require frequent inspection to see that such repairs are performed, they are entrusted to, and considered as the property of the parish in which they are situated. The parish appoints an officer or surveyor, whose duty it is to frequently examine the roads; to give directions to such labourers as may be necessary for their repair, and to provide and appropriate the necessary materials. The labour, together with the necessary transportation of materials by carts and horses, is provided by the inhabitants of the parish, and in order that it may be evenly and fairly distributed among them, an assessment is made upon every householder, according to the extent of the property he holds in the parish. And as this assessment is made by the inhabitants themselves, there is seldom any dispute as to its equity. According to the property of the inhabitant, or the extent of his use of the road, (if more than ordinary,) he has to furnish a certain number of labourers, horses, and carts, for a certain number of days in each year; and they are liable to be called out when the surveyor has occasion for their services, and the entire portion of that labour being completed at any time, he is not liable to be again called upon in that year. The labour, horse hire, &c., is also estimated in money, so that if it is not convenient to afford the assistance in kind when required, he may compound for it in money, which enables the surveyor to hire other assistance. These cash payments likewise fall upon such inhabitants as, notwithstanding their possession of property, may not have workmen or teams; and who, consequently, could not contribute at all, unless they were allowed to do so in money. When parishes become large and the above operation might prove intricate and troublesome, the labour finding system is wholly abolished, and a general money-rate substituted in its place; so that the surveyor has to hire all his hands and teams, and to purchase or dig his own materials. This is, in general, found to be the most beneficial mode of proceeding; because the surveyor can, in this case, pick out and retain good hands, who become accustomed to their business, and work willingly and cheerfully; and experience fully shows that a few good hands who are accustomed to working on a road will do more good to it in a shorter time than a greater number of unwilling hands not acquainted with the business. By the former plan there must be a succession of strange and uninstructed labourers, who may be said to be unwilling, because country labourers, in general, do not like to be put out of their regular routine of agricultural business, and especially to go to a work that they deem compulsory, and which, in many cases, is to produce a greater benefit to their neighbours than to themselves. Still, however, by the one or other process, parish roads are generally kept in a state of very fair condition.

The next and most important class of roads are those which, in Britain, are called the *high* or *turnpike roads*. These are the great travelling roads which go from the metropolis, in as straight lines as can be obtained, through all the principal towns and villages to the extremities of the country; and likewise from one principal town to another. As these roads are for the accommodation of the general public, it would be unjust that the expense of their maintenance and repairs should fall upon the parishes through which they pass; and, accordingly, these roads are supported solely by tolls, taken from all passengers that use them with cattle or carriages, and they are called *turnpike roads*, because they have gates called *turnpike gates*, and collecting houses placed upon them at certain distances, and the tolls there collected furnish funds for the preservation and repair of the road.

As these roads are of great national importance, they are all established and regulated by acts of the legislature. These acts impose penalties upon all persons obstructing the roads, and limit the maximum amount of tolls to be taken from the public, by which imposition is prevented, and the payment of the tolls is made peremptory; for the collector has the right of retaining a horse or other animal in the event of refusal to pay the toll, until it shall be paid. As foot passengers are not liable to toll, of course no provisions are made respecting them, except that they shall not damage or impede the road in any way. The property and management of these roads is vested in trustees, consisting of a number of the most wealthy, active, and responsible gentry and farmers that live in the vicinity of the road. The length of road confided to any one trust is never very long, and seldom exceeds from 10 to 20 miles in any one direct distance; but all the side or cross-roads that branch out of the principal road, and are subject to tolls under the same act of parliament, are included in the same trust, and each trust acts under a separate and distinct act of its own. A turnpike road, consequently, of several hundred miles in length, would be divided into a great number of separate trusts, the one beginning where the other terminates;

and as the trustees are selected from persons dispersed over the whole extent of the trust road, the certainty of having the whole length under the inspection of interested persons is thus secured, without imposing upon them the trouble of going far from their own homes. Each trust elects a clerk and a treasurer. The clerk is generally a respectable attorney residing in the principal town upon the trust road, and he is the secretary and executive of the trustees, to see all the orders they may issue duly carried into effect, and is in fact the representative of the trustees in the interval of their sessions, but has no power to act otherwise than under the directions of the board, unless such power is specially conferred upon him by them for particular purposes. The act of parliament constituting the trust, usually confers the power of suing and being sued at law, in the name of the trust, upon the clerk for the time being.

The funds are raised by tolls charged upon all horses, carriages, and droves of sheep, oxen, &c,. that use the road. These tolls are limited in their extent, though not always fixed by the acts of parliament that raise the trust; because if the trustees find they can keep the road in good order with a less sum than the maximum tolls will produce, they have the option of lowering the sum, though they have no power of augmenting it without a new act of parliament, which cannot be obtained except on proof that the maximum toll is insufficient to insure comfort and safety to the public. In this way the trustees can at all times make their available income accordant with their necessary expenditure, and they can have no interest in making it larger, because the money raised can in no case be appropriated to any other purpose than the maintenance and repairs of the road in their particular charge. These tolls are collected at gates which stretch across the road, and have a small house for the collector adjoining them, as in this country. In roads of much traffic, these gates, for the sake of expedition, are never closed during the day, and the collector is constantly at his post, but they are shut and locked at night, though the collector is bound to rise and open them at all hours to any one desirous of passing: and he can shut the gate and refuse passage to any one who objects to paying the toll, which, to prevent imposition, is required by law to be painted and set forth in letters at least one inch high, on a board at the side of the gate. In England these tolls are only payable once in a day of twenty-four hours, except in a few instances of bridges; so that having once paid the toll a passenger can go backwards and forwards as many times as he pleases between twelve o'clock on one night and the same hour on the following one. To prevent a repetition of the demand, the collector is bound to give a printed pass ticket, with the name of the gate and a number, letter of the alphabet, or some private mark upon it, to a person on first paying the toll, and the reproduction of this ticket exempts him from further demand that day. The letter or private mark is changed every day, so that the ticket of one day will not pass for another.

The trusts upon all roads, and even upon the same road, are perfectly distinct and separate from each other, and they have no interference; consequently each trust is compelled to raise its own funds, and it does this by having its own toll-gates. Every trust must, therefore, have at least one toll-gate on each of its principal and branch roads; or if the trustees do not think proper to collect the whole sum they are authorized to take, at one spot, they may divide that sum, and receive one part of it at one part of the road and the remainder at another. This accounts for the number of toll-gates met with in Britain,—a circumstance that always strikes travellers from strange countries with surprise. Still the principle is good, for if the number of gates is large, the sum taken at each of them is small in comparison to what it must be to raise a similar sum of money with fewer collectors. No person can travel one of these roads for more than ten or twelve miles, without being called upon to pay a toll for the road he is using, and thus the burthen of keeping those roads in repair becomes very much divided among the whole travelling community.

The heaviest expense incident to the English system of turnpike roads, is the maintenance of the toll-collectors, who must be stationed at the many gates, and the apparent liability that may exist of the trustees being defrauded out of a great part of their revenue by their dishonesty, if they do not account for all the money they may receive, or from their being careless and wanting in vigilance in making their collections. This is met and obviated by the trustees never keeping the collection of the tolls in their own hands, but by farming or letting them out by auction for stated periods, to such collectors as will make the highest bidding; such periods being never shorter than one, or longer than three years. Road trustees are, in some cases, allowed to retain a certain limited fund of reserve out at interest on government security, to provide for alterations, amendments, and improvements, where they are likely to occur. And in the event of requiring a sum of money suddenly for such purposes, the tolls are frequently mortgaged, and are considered a full and efficient security for such loans.

The first principles that should govern the formation of roads, are proximity and facility of passage. The first is attained by making the road of communication as nearly right lined as possible whenever the country it has to pass over is so level as to admit of it; but the right lined direction should not be presevered in, when it is hilly and uneven, since a more circuitous route over a level tract of country is better than the shorter one that is hilly, whenever the elevations and depressions of the soil are so extensive as to become inconvenient to the passenger. The operation of *levelling*, and thereby selecting a good and favourable line, is therefore of the greatest utility and importance in selecting a good line of road.

Another and most important subject to be attended to in the selection of a line of road, is its drainage. Many old roads will be found sunk beneath the general surface of the adjacent land, notwithstanding this is the worst principle of construction, and one which no pains should be spared to avoid. As a general rule, every road should be kept above the soil over which it passes if possible; and, whenever this cannot be effected, its surface should be enough of a hill to cause water to run down it; or, if level, it should have side ditches or water-courses, to carry off rains as speedily as possible. Common observation will convince any one that a road formed of almost any ordinary soil, without gravel or any thing to cover and protect it, will be good, provided it is so elevated and drained, that rain water will not remain upon it; while, on the contrary, a sunk road, or one formed like a wide ditch or shallow canal, will be soft and bad, and will wear

into holes or ruts, even if formed of the very best materials, and the greatest pains should be taken for its preservation. For the same reason, a good road is scarcely ever met with in a thick wood, merely because the foliage shuts off the sun's rays, and by excluding them, and a free circulation of air, prevents that evaporation that would otherwise take place. Perfect drainage must therefore be considered as the great and leading requisite to the existence and maintenance of a good road, and this ought therefore to be the great object of attention to the engineer in the setting out new roads, and the amendment of those that already exist. It may frequently be difficult of attainment, especially in level countries; but we will endeavour to give such directions as seem most likely to assist in attaining this most essential object.

No road should be formed in a hollow or concave form, or even be quite flat upon the surface of its transverse section, but, on the contrary, should be convex or protuberant along its central line. If the centre of a road of 20 feet wide, is made 6 inches higher than its two sides, this will keep the middle dry, by throwing the water to the two sides. This rising or convexity in the centre, is called the *crown of the road*, and as 6 inches is the twentieth part of 10 feet, or the half-width of the road, the crown would be said to rise 1 in 20, and a proportionate elevation should be given to the transverse section of every road, whether it is narrow or wide. Such a convexity will occasion no danger to carriages running upon it, or any inconvenience. If such a road is above the level of the adjacent land, the water may be discharged from its two sides without inconvenience, or it may be conveyed into ditches sunk on the sides of the road and running parallel to it. In level countries, difficulties may arise in getting the water discharged out of these ditches, and they may require to be made very deep in the progress of their fall; still, it seldom happens, but that a vent or discharge of some kind may be discovered in the progress of a few hundred yards; and, should that prove impossible, ponds or reservoirs may be sunk in the lowest pieces of land that can be found, in which the water may sink into the land, or be dissipated in evaporation. A very small fall or descent will be sufficient for road ditches. They should begin at the surface, or have scarcely any perceptible depth at the upper part of the road, and become gradually deeper and wider as they descend; and all the soil dug from such ditches should be thrown on to the road to elevate it, instead of being thrown on the outside of it, as frequently practised.

Whenever it may be necessary to sink deep ditches by the side of a road, they ought always to be separated from it by a foot-path or causeway, raised from nine to twelve inches at least above the road, to prevent accidents to cattle or carriages that might fall into them; the water in this case being conveyed from the road by drains passing through such causeway; and, whenever for the purpose of drainage, it may be necessary to convey water from one side of a road to the other, it should always be carried by a drain or brick culvert running under the road, and in no case be allowed to flow freely over its surface.

A perfectly level road is by no means desirable, on account of its property of retaining water; and, as a very slight slope or inclination in the longitudinal direction will be sufficient to produce a discharge of water to the lowest part, while it will hardly be perceptible in its effect upon the draught of carriages, so it ought always to be obtained. By a judicious selection of line, and setting out of a road, sufficient slope may generally be found on the natural ground; but if that is impossible, it must be produced in the earth-work, that is to say, in the slight cutting or excavation that is always necessary for rendering the surface of the ground smooth and uniform, and fit for the hard materials that have to be laid upon it; and by distributing the soil that should be excavated from one or both sides, for draining ditches. Instead of throwing the soil thus obtained upon that part of the road nearest to where it is produced, it may often have to be conveyed a considerable distance; and, whenever that proves necessary, carting the soil in common or three wheel carts, will be found more expeditious and cheap, than moving it by barrows, notwithstanding that barrows are preferable for short distances. The least slope that a road called level should have, is a yard perpendicular in a mile of length; but, as so slight a slope as this will barely affect the water, two, three, or even four yards in a mile, will be better, and will produce a sensible run or discharge of the water. A greater slope should be avoided if possible; because, when the slope is rapid, the water of hard rains runs with such velocity and force, as to wash away part of the materials that compose the roads or side-banks.

As to the width of roads, no rule has ever been adopted, since they should be made suitable to the kind of traffic expected upon them. As a cart or carriage can pass upon a track 8 feet wide, and 3 feet more allows a foot passenger, or even a horseman to pass, many roads or lanes are found that do not exceed 11 or 12 feet in width; but this is a very bad plan, and one that should constantly be avoided, unless in deep cutting, tunnels, or other positions, in which, from local circumstances, such confined width is rendered necessary. It precludes the possibility of good drainage or repair, and when two carriages meet in opposite directions, is productive of serious inconveniences, even if occasional wider passing places may have been provided. Such narrow roads are only made with a view to economy, but it is economy of a false kind; for, if the wheels of heavily laden carriages are con-

strained, by the narrow limits of the road, to move constantly in the same track, they cannot fail to wear it out, and fill it with deep ruts and inequalities in a short time; and the ruts and holes, by holding water, soften the adjacent parts, and frequently render the whole impassable; while, on the contrary, if width had been allowed, when one track becomes bad, another is adopted. The vehicles, instead of continuing in one straight forward course, change from one track to another, thus traversing the ruts and inequalities obliquely, which has the effect of tending to flatten or fill them up; and thus a road that is wide, and has considerable traffic upon it, in some measure, repairs itself, of which there is abundant evidence in many country places, where the roads are little attended to. No road should, therefore, ever be made less than 24 feet in width for any purpose, and in those that are much frequented, from 30 to 60 feet will not be found too much.

Notwithstanding a perfectly straight line forms the nearest communication between one place and another, and can very frequently be obtained in setting out a road, still, if it continues for miles in succession, it is generally admitted to be irksome to the traveller; and, as a gentle undulation or waving of the line produces very little addition to the length, and adds to the beauty of a road, it may be safely admitted, and will in general be approved. When the necessity occurs of a road changing its direction, it should never do so abruptly, but in the form of a long and gentle curve, such a line being more safe and consistent with rapid travelling, than sudden turns, which ought only to be admitted where one road crosses another, and then sufficient space should be left at the intersection to admit of carriages taking such curved direction; and, in every case a certain distance of the road in advance, should be open to view, to avoid the unexpected meeting of what may be moving in an opposite direction. Guide posts, indicating the place a road leads to, should also be set up at all intersections of roads. They are often disregarded by local inhabitants, as being useless to those who, living in the neighbourhood, know every road, but they are highly useful, and save much time and anxiety to strange travellers. In England the road trustees and parishes are bound, by law, to provide and maintain them as part of the road expenses; and the plan lately adopted for making them is good and convenient. The indices, or pointers, fixed to the top of the post, instead of being made of wood with the place painted upon it, (and which is very apt to be defaced,) is made of cast iron, and consists only of letters about three inches high, attached to the surrounding frame, so that no ground or board is necessary, but the whole is transparent with the exception of the letters, and these being seen against the sky, can be read after it is so dark that no other writing would be visible.

In all great roads, mile stones should be set up to indicate the distances to and from places; and these, of course, are placed at intervals of one mile asunder. Formerly the distances were indicated by posts of wood, painted; but these being subject to rapid decay and obliteration, were replaced by stone posts; which, although durable in themselves, are not so in their inscriptions. They might answer if formed of marble or any good stone for maintaining carving, but in many parts they have been formed of the nearest local stone, to avoid the expense of transportation, and the consequence is that many of them are illegible. Of late years, cast iron has been resorted to, and is found to answer the purpose in a more satisfactory manner than any material previously resorted to. They do not require great strength or weight of metal, and are often fixed upon the face of the old ponderous stone. The casting consists of two flat sides about fifteen inches wide, and about three and a half feet high out of the ground, placed at right angles to each other, and united at the top by a triangular piece that slopes so as to make an angle with the horizon of about 60°. The whole is cast in one piece, and the letters stand out, or are in relief. The large figure on the top is the distance from the metropolis, London, and the two sides present the distance from the nearest post towns in the two directions of the road. Being hollow, they may be attached to a post of stone or wood, or the cast iron may be prolonged sufficiently to be set in the ground. They are painted white, and the letters black, so as to be seen at a distance, and are not only exempt from obliteration, but are cheaper, and, it is believed, better than any previous method of marking the distance upon roads.

In many places roads are unavoidably subject to floods, or freshets, so as to become occasionally covered with water. When this is the case, the proper direction of such road should be indicated by posts placed at convenient distances along their sides, with figures, cut or painted upon them at every foot from their bases, so as not only to guide the traveller in his proper track, but to inform him what depth of water he has to pass through.

Trees and live hedges are, without doubt, pleasing to the eye, and add much to the beauty of a road, but at the same time, they are highly detrimental to it, particularly if placed at the south or sunny side. Hedges, therefore, should be kept low by cutting, and trees ought not to be permitted, particularly if their branches are long and overhang the road. Many advocate the planting of a road side, on account of the pleasant shade produced, which is desirable during the hot season; but if trees are sufficiently large for this purpose in the summer, they will inevitably produce more than an equivalent mischief in

winter or wet seasons, by their retention of water, and dripping upon the road, as well as preventing its becoming dry when the rain has ceased. A good piece of road overshadowed by trees, is a thing of very rare occurrence.

It only remains to speak of the manner of rendering roads hard and durable after they have been set out and formed as before directed, and this can only be accomplished by covering them with hard materials. What these materials will be must in general depend on the locality of the road, and its happening to be in a completely inland country, or one that has the advantage of navigation. There is no doubt but that the hardest flint stones make the best road, and next to them the whin stone, trap and basaltic formations, but they are not procurable in all places, and therefore the best materials that can be obtained in the immediate neighbourhood must be resorted to, and in their selection, hardness and tenacity are the great objects to be regarded. When countries are near navigable rivers or canals, it often proves more economical to transport hard materials from a distance, than to use the softer ones with which a country abounds. No material is more universally distributed over the face of the earth than what is called gravel, and accordingly that is generally used for making roads. Gravel is a general term applied to all stones that have the form of pebbles, whatever their composition may be, therefore it is not admitted as the name or character of any particular stone in mineralogy. The hypothesis usually held respecting pebbles is, that they are fragments of rock broken or separated from the large masses, by decay of parts, or by some great convulsion of nature, and that they have been rounded by having their points and sharp edges worn off by attrition in the sea, from whence they have been deposited, by means of which we have no record, in various parts of the dry land, and frequently at elevations far above the present reach of the sea. These pebbles, therefore, vary much in quality, even in the same parcel of gravel, but they are almost universally hard, because the process they must have undergone to bring them to the form of pebbles would grind the softer materials to a state of powder, producing either sand or common soil; and as flint is the hardest of all common or ordinary stones, so the pebbles of gravel are usually of this material. What may be designated under the general name of *gravel*, is divided into several classes, by names dependent only on the magnitude of the component parts. Thus large rounded pebbles, which are never quite round, but are flattened on their two opposite sides, and which are found abundantly on many sea shores, of a magnitude varying from that of a man's fist to his head, are called *boulders*, and these are picked up separately and reserved for the purpose of paving streets. What is generally understood by gravel has no stones in it larger than the fist, but it has all gradations of smaller ones down to sand. The sort always used, or at any rate preferred for road making, is termed clean, or screened gravel, that is to say, the mixed gravel passed through a screen or sieve composed of very strong iron wires, or rather thin rods of iron placed at from half to three-quarters of an inch asunder. All that will not pass through such a screen is termed screened gravel, and that which does pass through is, by workmen, termed *hoggin*. The first is alone used for road making, and the latter for covering causeways, footpaths, and gravel walks; it consists of a mixture of sand and small pebbles, which bind together and produce a hard, smooth, and compact surface.

The old system of road making, or rather road covering and repairing, as followed in England, and which is still persevered in in many places, was, after having prepared the ground or sole of the road by giving it its proper crown or convexity, slope, water tables, and so on, to cart and spread as much screened gravel, without any previous preparation, as would cover the whole road to a depth of from nine to twelve inches, and then to cover this with a thin coat of hoggin, in order to fill up the interstices, and cause the gravel to bind or become compact. This produced a very rough road at first, but by time and use it would become compact and tolerably smooth. In this way it was left until it needed repair, and that repair consisted in first scraping off all soft mud, and then applying another coat of screened gravel without hoggin, so as to cover the old road to a thickness of two or three inches, spreading it by rakes or shovels, to make the surface as even as possible, and to fill up the old ruts and inequalities, and this was repeated every fall or autumn. This practice was continued until Mr. M'Adam, of Scotland, drew the attention of the public to its waste and impropriety, and introduced his improved system of road making, which he began about the year 1810, and which is now almost universally followed. He was led to the consideration of this subject by observing the effect that took place when a heavy carriage, such as a loaded stage-coach, passed over a newly formed road. The wheels being thin and narrow, cut or sunk into the new gravel to a considerable depth, so as to make the draught enormously heavy, and they were permitted thus to sink in, on account of all the gravel pebbles being hard and round, which allowed them to roll about and displace each other, thus completely counteracting any tendency they might have to bind or unite together into a hard mass. Every vehicle that passed in succession produced a new disturbance or displacement of the materials, to such an extent that it might almost be compared to ploughing up the road; nor did the road begin to assume a good and hard aspect, until by the repeated passage of heavy carriages over the materials they were broken and partly reduced to powder. In the same way when a road was repaired by giving it a new coat of coarse gravel, without disturbing the old surface, the wheels constantly made their way through that new coating down to the old surface, displacing the new gravel, unless it was applied in a very thick and expensive manner, and thus the repairs never availed until the new material was partly worn out, as it was supposed, by becoming broken. In the formation of his system he was guided alone by what he saw going on in nature. If the road did not become hard and good until the stones were irregularly broken by the frequent passage of heavy carriages over them in process of time, why impose the duty of breaking the stones upon the carriages,

when it could be more speedily, effectually, and regularly done in the first instance, by hand labour? Again observing that when a carriage wheel, or even a horse's foot fell upon a large stone that was imperfectly bedded or fixed in its place, such stone would be moved, or perhaps turned over, by which a disturbance of all the smaller stones around it took place, and they became loosened and disturbed, he became satisfied that no large stones should be used. The leading feature in M'Adam's system of road making, therefore, is that no large stone, or stone of a spherical or rounded form, however small, should be introduced into the formation of a road, but that the operation of breaking them should be resorted to in the first instance, before they were used upon the road; thus not only reducing them to small magnitude but likewise producing sharp points and angular edges upon them, in order that they might lock into each other, and nearly, if not quite, destroy their tendency to roll about or give way to pressure; and this has been attended with the happiest result, for a bed of broken stone of much less thickness than the gravel formerly used, is found to consolidate sooner, and to produce a much more durable and compact surface than could be formerly obtained; besides which, the broken stones preserve the form in which they are placed upon the road, while in the old plan the rounded pebbles had a constant tendency to shift from the middle of the road, which is most used, towards the sides, thus requiring the occasional use of the hoe and rake for several weeks, to draw them to their former places.

Another objection to the use of rough or unprepared gravel arises from the various dimensions of its component parts. The small and fine stuff has a tendency to set to the bottom, while the large stones work out to the surface, and occasion inconvenience and irregularity, with great additional wear and tear to wheel carriages, until they are broken down; while in the M'Adam plan, as all the stones are reduced to nearly the same size, this effect cannot take place.

Mr. M'Adam also adopted a new system in the repair of former roads, although one of his principles was that a road should never be permitted to get out of repair, which may be effected for a long period, by care and watchfulness. The method of obtaining this desirable end is by having single cart loads or small heaps of ready broken stone disposed at short distances upon convenient places on the waste ground at the sides of finished roads, or wherever they would be out of the way of passengers, and keeping a single labourer to inspect a certain distance of road, who, with a wheelbarrow and shovel could take the few stones necessary to fill up a cavity or rut as soon as it appeared, from the pile nearest to it, and thus by keeping the whole level, none of those concussions of heavy loads occurred, that are more hurtful to roads than anything else. A road suffers little from a heavy load drawn upon it, provided the surface is smooth and regular; but when ruts or holes occur, the wheel sinks into these with all the increased momentum of the fall, and produces an effect that may be compared to that of a prodigiously heavy hammer falling upon the spot: and thus the hardest materials soon crush and are ground to dust, while no such effect occurs on the road while kept with a smooth and even surface.

Still, however, the materials will wear out and give way in time, so as to require renewal, and whenever this has to be done, broken stone alone is to be resorted to; but instead of placing it upon the old smooth surface, as formerly done, and where a very imperfect incorporation took place between the old and hard surface and the loose new materials, he prepares the former road by picking up its top surface with a short and heavy pickaxe to a depth of at least two inches, so as to render it quite rough, or like a newly formed road in appearance, and upon spreading the new stone to a depth of three or four inches upon it, a complete binding and incorporation takes place in a very short time. To this process he therefore applied the new name of *lifting* a road instead of repairing it, though in fact, the lifting only applies to the raising of the old surface to prepare it for proper incorporation with the new material. The road being repaired, has to be watched as before stated, for a few weeks, to fill up any cavities that may occur, since it is impossible, either in making a new road or repairing an old one, to dispose the materials so equably as to ensure that one part shall not sink more than another; but when once these inequalities have been adjusted, and the whole surface has become uniformly hard and smooth, it may be left with confidence, as deep holes or ruts occur through negligence alone.

It may at first sight appear that the breaking of stones is a tedious and expensive process: so it is in the first instance, but it affords employment to old men and children who might not be otherwise employed, and the expense is amply repaid by the smaller quantity of stone required, and the little repair necessary to the road when once properly made. When first adopted, Mr. M'Adam used an iron ring as a gauge for the size of the stones, and no stone was considered to be broken small enough, unless it would pass through that ring. Now the stones are carted in their rough state to the road side. The labourers sit upon the heap, and selecting a large stone as an anvil, they break the larger ones upon it with a long steel hammer, taking one at a time, and throwing them, as broken, to one side. The work is paid for by the bushel of broken stone, and this being measured in the presence of the surveyor or his overseer, if he meets with any stones that the breaker cannot take between his teeth, the work is considered imperfectly done, and is not paid for until the heap has been gone over again. This is a sufficiently accurate gauge, and operates as a check upon the inattention of the workmen.

After a new road has been formed, or an old one repaired, Mr. M'Adam recommends the use of a very heavy cast iron roller to be drawn by horses over the newly laid stone, to render it more speedily solid and compact than it otherwise would be. But a roller of sufficient weight to do good, is so heavy and expensive that it is not always resorted to. Such a roller ought to be about six feet long by four or five feet in diameter, and full an inch and a half thick of metal, to be effective. And lastly, he insists, (as we have done,) in the absolute necessity of good and perfect drainage for every road; saying that if the substratum of natural soil is not kept dry and hard, we may in vain look for a perfect road, since the best materials will be pushed or driven down, and will be buried in the natural soil if soft, by every passing load, and in their passage downwards they raise and protrude a quantity of that soil, about equal to their own bulk on each side, which disturbs and mixes with the broken stones, and renders them unfit for their office, by destroying the foundation they should rest upon. Indeed, so essential it is to the preservation of a good road that it should be kept dry, that the mud or slush remaining on the surface of roads after continued rain, ought never to be permitted to remain and dry there, but should be scraped off and put in heaps at the sides of the road to dry. This scraping should be performed by wooden hoes, about a yard long, as iron ones draw up the stones and produce irregularity. The road stuff, when so collected and dried, forms the best sand for building mortar, and is in general very good for lining furnaces in which great heat is required, and also forms excellent foot-paths.

The greatest difficulty a road-maker has to contend with is a bad substratum or natural soil. If that is good and hard, and so situated that it can be drained, a good road may always be formed, especially if good gravel or other sufficiently hard material can be found to cover it. In clay countries, where gravel or stone of any kind is scarce, an artificial material may be formed (if wood abounds), by making the clay into balls and burning them until they are nearly vitrified. On the same principle, the slag or refuse from iron and other furnaces, makes an excellent material. In the neighbourhood of collieries, the stony or slaty part of coal is used, and in the south-west part of England many of the roads are formed wholly of hard or stone-chalk. In fact almost any thing, except sand, will make a tolerable road, if kept dry, properly scraped, cleansed and attended to, and the substratum is hard, dry, and absorbent. Hardness alone is not sufficient, for solid and compact rock is a very bad bottom, unless when covered by so thick a stratum of good material, as will prevent the surface water from sinking down to it, or its irregularities from being perceived. Rocky countries are generally very broken and hilly, and owing to the smooth surfaces presented, and the water being unable to penetrate into them, the materials will not adhere and become fixed, but are very liable to be washed away by the floods of rain, so frequent in such places. A sandy substratum is also difficult to conquer, except by such a thickness of gravel or broken stone as will entirely prevent any concussion or vibration that occurs at the top from being transmitted below. Should it take place, the lower stones will sink gradually into the sand, which will rise and mix with the upper stratum, thus making room for that to descend until the whole may be lost or buried. The most effectual method of counteracting this effect is to dig the sand out to about a foot in depth, and to place large and flat stones upon the bottom, so that they may take an extended bearing upon the sand; to fill in with large broken stones, or old brick rubbish, if it can be procured, and to finish with stones broken to the usual size. The worst bottom, however, that has to be contended with, is a bog-swamp or morass, in which the ground is soft and full of water, so as to be incapable of supporting small stones, and from which no drainage of the road-way can be obtained. It frequently happens on inspecting a situation, even like this, that some outlet may be found for draining off the top water of a morass, though, perhaps, only for a foot or two, and yet this will at times render the surface better, though it will generally sink or become lower when the water is drawn away from it. It is, however, advisable to drain it as far as possible, and that done, there is no better way of forming a road-way than by placing fascines (as they are called in the language of military engineering), or bundles of brushwood tied together and disposed regularly by the side of each other in the manner of paving, and then placing a second course above these, laid in the cross or opposite direction; the next, or third course, should be parallel to, and in the same direction as the first. The number of layers or courses of these fascines will, of course, depend on the nature of the place, and the quantity of sinking or depression that will take place when they are loaded with gravel. Should the place be very bad, two or three courses may be laid, and then covered with small poles or young trees, laid across the intended road-way (in the manner practised in America in wet and soft places), when other courses of fascines or faggots should be laid upon them; the only use of the poles being to bind the whole together, and prevent the possibility of one part sinking without another, thus extending the pressure over a considerable quantity of surface. The platform of fascines, being thus formed, should be covered with large and flat stones if they can be procured, and a thin stratum of loam or clay, that is nearly impervious to water, is sometimes laid over them, after which the road is gravelled or covered with stone, in the usual manner. The weight of the road materials will generally cause the fascines to sink in the soft bottom until they disappear, and sometimes even the whole road may sink to such an extent as to become useless; and the only way of recovering it is to repeat the former process until a good and hard road is obtained. This is a very expensive mode of proceeding, and one which, of course, would never be adopted, except when local circumstances render it absolutely necessary; because, in most instances, it would be better, and probably, cheaper to go a few miles round, than to cross directly over a bog or morass. See the article PAVING.

ROAD-SCRAPINGS. The mud raked and shovelled from carriage roads. It varies exceedingly in composition, according to the nature of the stones or gravel or other stuff of which the roads are made, and to the amount of animal excrement which is dropped upon them; but, in every case, it possesses considerable manurial powers, and is a good material for forming composts, particularly to clay lands. See the article COMPOST.

ROAN-TREE. See ASH (MOUNTAIN).

ROARING. A disease in horses, who, in consequence of it, are popularly called roarers. See the article BROKEN-WIND.

ROAST-BEEF PLANT. See IRIS.

ROBIN. See REDBREAST.

ROBINIA. See ACACIA-TREE.

ROCAMBOLE,—botanically *Allium Scorodoprasum*. A hardy, bulbous-rooted, culinary plant, of the garlic genus. It is used in salads, and as a pot-herb, and is sometimes called Spanish garlic, but is milder than common garlic. It was introduced to Britain from Denmark toward the

close of the 16th century. Its root comprises a cluster of cloves or bulbs like garlic; its stem is about 3 feet high, and bears at its top many small cloves which, as well as those of the root, are used for culinary purposes; and its flowers have a light purple colour, and bloom in July. A very small bed of this plant affords a sufficient supply to the largest family. The separated root-cloves may be planted by dibbling in February, March, or April; and they will acquire full growth in July or August.—A taller species of garlic, with pale red flowers, a native of Greece, and introduced thence to Britain, *Allium ophioscorodon*, is also sometimes called rocambole.

ROCCELLA. See Orchil.

ROCHEA. A small genus of ornamental, evergreen, shrubby greenhouse plants, of the crassulaceous order. The sickle-leaved species, *R. falcata*—called by Linnæus *Crassula falcata*—was introduced to Britain about 53 years ago from the Cape of Good Hope. It has a height of about 3 feet, and blooms from June till September. It thrives best in a mixture of loam and peat and sand, and loves a full exposure to the heat and light of the sun's rays.—The perfoliate species, *R. perfoliata*, is taller than the preceding, and comprises two kinds with respectively scarlet and white flowers.

ROCHELLE SALT. The tartrate of soda and potash. It is a pharmaceutical preparation; and occurs in large, regular, hard, transparent, prismatic, six-sided or even ten or twelve-sided crystals; and has a bitterish saline taste; and acts as a mild and cooling cathartic.

ROCKET,—botanically *Hesperis*. A genus of ornamental herbaceous plants, of the cruciferous order. One species grows wild in Britain; nearly 20 have been introduced from other countries; and a few more are known. All the kinds in Britain are hardy; and they vary in height from 6 inches to 4 or 5 feet; and two are annuals, six or seven are perennials, and the rest are biennials.

The matronly rocket, *Hesperis matronalis*, concentrates in itself the chief interest of the genus; and is par excellence the rocket of all sorts of common flower-gardens. It is a native of Italy, and was introduced to Britain toward the close of the 16th century. Its stem is erect, and has a height of from 1½ to nearly 5 feet according to the variety and the culture; its leaves sit close to the stem, and are spear-shaped, pointed, and dentated; and its flowers come out in a loose thyrse on the top of the stem, and have a deep purple colour, and emit a delightfully sweet fragrance, especially in the evening or in cloudy weather, and bloom from May till August. It may be regarded either as a long-lived biennial or as a very short-lived perennial; and, in all its varieties, especially in the finer ones, it is most conveniently and effectively propagated by division of the roots; and the new plants of it are particularly vigorous and handsome when they are raised from roots whose stems have been headed down and prevented from flowering. Its best and most distinct varieties are the white-flowered, the double white-flowered, the double red-flowered, the variegated double-flowered, and the leaf-flowered; and good plants of some of these carry close, dense spikes of flowers, somewhat in the style of prime double-flowered stocks. The matronly rocket is said by Boerhaave to be anti-scorbutic and diaphoretic, and of great service in asthmas, coughs, and convulsions; and it has been recommended also as an external application in cases of cancer, gangrene, inflammation, and contagious diseases; but it does not appear to have really any appreciable medicinal virtue. —The indigenous rocket, *Hesperis inodora*, inhabits the pastures of some parts of Britain; and very much resembles the matronly rocket, and is ranked by Decandolle as merely a variety of it, and has a place by the side of it in some gardens; but its flowers are pink-coloured, and have no fragrance, and do not continue so long in bloom.

ROCKET,—botanically *Eruca*. A small genus of hardy annual plants, of the cruciferous order. The cultivated species, *Eruca sativa*,—called by Linnæus *Brassica eruca*,—is a native of the South of Europe, and was introduced to Britain in the latter part of the 16th century; and it comprises eight or nine varieties, all of which were formerly in some request as salad plants. Its leaves rise numerously from the root-crown, and are spear-shaped and indented and 4 or 5 inches long, and spread on the ground; its flower-stem is solitary, and rises to the height of from 12 to 21 inches; and its flowers grow in loose bunches at the top of the stem, and are white in some varieties, yellow in others, and pale yellow in others, and are succeeded by long two-celled pods, filled with small round seeds. When this plant is used as a salad, it requires to be eaten young, and only in winter or spring; for it is too strong and rank when old or in summer or autumn. Its qualities, in fact, are too biting; and gave rise to the name eruca, from a word signifying to burn; and have eventually brought it into general neglect. It formerly took rank among medicinal plants as a good diuretic.

ROCKET (Cress). See Cress-Rocket.

ROCKET (Sea). See Cakile.

ROCK-ROSE. See Cistus.

RODRIGUEZIA. A genus of ornamental, epiphytous, tropical plants, of the vanda division of the orchidaceous order. The side-flowering species, *R. secunda*, is an elegant, red-flowered, October-blooming plant of a few inches in height, and was introduced to Britain about 30 years ago from South America. The crisped species, *R. crispa*, has singular-looking crisped flowers, of a dull sea-green colour, bordered with yellow, and emitting a fragrance similar to that of the primrose; and was introduced to Britain 10 or 12 years ago from the Organ mountains of Brazil. Several other species have been introduced.

ROELLA. A genus of ornamental Cape-of-Good-Hope plants, of the bellflower family. Six or seven species, chiefly blue-flowered summer-bloomers of about a foot in height, some annual and others perennial, some herbaceous and others ligneous, have been introduced to the gardens of Britain.

ROHAN. An artificial pace of specially-trained riding-horses in Egypt and Turkey. It resembles the amble in easy effect, but differs essentially from it in character, and gives the horse an awkward, straddling, broken-backed appearance. It is produced by so loading the pasterns of the hind legs with metallic discs as to prevent the fetlock-joints from bending, and to cause their office to be peformed by other portions of the limb; and it, in consequence, renders the foot-fall comparatively soft and the seat of the rider comparatively free from concussion; and, when it is fairly formed, the metallic discs are removed.

ROLLER,—scientifically *Coracias*. A genus of birds, of the crow division of passerinæ. The common roller, *C. garrula*, is an occasional visitor of the shores of Britain. It is about the size of the jay, and has a total length of 13 inches. Its general plumage is sea-green and various shades of blue; its back and scapulars are fawn-coloured; the tip of its wing is pure blue; and several parts of its body are tinged with verditer, brown, and black. It is a very wild bird, though sociable enough with its fellows; it is noisy, and builds in the hollows of trees, and migrates in winter; and it feeds on worms, slugs, insects, small frogs, and berries.

ROLLER. An implement for compressing, smoothing, pulverizing, or otherwise finishing-off cultivated land, whether in grass or in tillage, in preparation for sowing or subsequent to sowing, in a newly sown state or after the appearance of the nascent crop. Both the forms and the uses of the roller, in fact, are exceedingly diversified; and some of the most useful implements of the roller class differ so very widely from all the old and common rollers, and at the same time from one another, as to take to themselves peculiar names, such as drill-roller, seam-presser, and clod-crusher.

All the old or early rollers were simply cylinders, and may be supposed to have been employed only for breaking down the cloddy and lumpy portions of tilled stiff soil preparatory to sowing, and for compressing and smoothing and consolidating light and driftable lands immediately subsequent to sowing; and such rollers are still confined to the same principal uses, with the addition of the smoothing and compressing of grass lands. They are thought by some writers to have come into existence coevally with the plough, or with the rudest stirrer of the soil, or at least to have appeared immediately after it,—and certainly they occur in countries where agricultural processes are in a very rude and almost nascent state; yet they are assigned by other writers to an epoch later than the harrow, and even than the grubber,—or to one in which the pressure of increasing population drove farmers by necessity to the cultivation of stubborn and adhesive soils, and compelled them to invent mechanical means for breaking hard clay clods. The cylindrical roller, at all events, is known to have been till recent times the only implement of its class; and though this might seem to a superficial thinker to have been quite simple and unique and incapable of variety, it really received, in the course of time, a great diversity of size and weight and construction, and was made first entirely of wood, then of stone with a wooden frame, and then in various ways of iron, and came at last to be formed of two or three or more parts, revolving either on the same axle or on independent axles.

The common rollers, or land-rollers, of the present day comprise all the varieties which have ever been used, except the most rude and ancient. The wooden ones are either pieces of heavy solid timber, of the full diameter of a large tree, or hollow cylinders, variously constructed, and of comparatively large diameter; and though they make little impression on any but very light soils, they are highly serviceable for levelling potato or turnip drills, for compressing the earth about newly sown seeds, and for some other and analogous light purposes. Some are spiked with iron or encircled with large metallic rings, to assist in crushing clods; many or most have simple contrivances, generally a weight-containing box on the upper part of the frame, for temporarily increasing their weight and pressure; and all are mounted with a skeleton cart-like frame, terminating in shafts for one or two horses, or with attachments for four or even six oxen, according to their respective size and weight. The common solid wooden rollers of England are usually made of oak or ash, and generally vary from 5 to 7½ feet in length, from 16 to 20 inches in diameter, and from 10 to 15 cwt. in weight, but occasionally are 9 feet in length, from 20 to 30 inches in diameter, and so heavy as to require to be drawn by 4 horses or 6 oxen. A very common roller in Scotland 20 or 30 years ago, and one most easily and cheaply procured, had a wooden axle, with two or three rows of spokes placed in it according to its length, and felloes placed on the extremity of the spokes in the manner of a cart-wheel, and planks or boards of wood fastened on the felloes all round; and a closely similar roller, of still more facile construction, is now occasionally made in England, with three broad wheels of the required diameter,—two of them placed at the ends and the other in the middle of the required length,—and with an iron axle passing through the whole, and adjusting them to their positions, and with strong, narrow, bevelled planks nailed firmly lengthwise round all the exterior. Some hollow wooden rollers

have an octagonal instead of a circular circumference; and they do their work better than the circular ones, on account of each turn laying the flat surface with a momentum on the ground; but they require a greater power of draught. Many wooden rollers, also, as well as many stone and many iron ones, are double, or consist of two pieces, placed in one frame, and performing the same action as one piece, but rolling independently of each other; and not only are these much more convenient in turning than single rollers, and less severe on the team, but they are more suitable for light soils or corn crops or sown grass, in consequence of their neither tearing up the ground nor injuring the young plants at the end of a field.

Stone rollers of granite, or of hard, compact, crystalline trap, are very common in districts which abound with these materials, and are both very cheap and very efficient. They are usually made of from 12 to 16 inches in diameter; and, including the cost of both frame and scraper, they are sometimes from 5 to 10 times cheaper than equally efficient wooden ones, or from 8 to 12 times cheaper than equally efficient iron ones. They have the high advantage also of being easily and cheaply obtained of a great diversity of size and weight and mutually proportional length and diameter; so that from 5 to 12 of them of different kinds, in adaptation to different soils or different states of soil or different kinds and conditions of land and crop, may be kept on a farm for the price of a single roller of iron or of wood.

Iron rollers of the common cylindrical kind are the most common for gravel-walks, lawns, parks, and other land-surfaces which require to be kept firm and smooth; and they are also common for ordinary agricultural purposes, in some districts which are destitute of granite or compact trap; and they possess the advantage of admitting a temporary increase of their pressure by means of suspending weights on their axis. They are made of great diversity of size and proportions to suit a corresponding diversity of tastes and purposes; and one of the most approved, for ordinary agricultural uses, is double, or has two separately revolving parts, and weighs from 10 to 15 cwt., and is drawn by two horses; while another has three separate cylinders, each about two feet in diameter, and of the same length. As cast-iron rollers are liable to fracture when drawn along a rough road, in transit from one field to another, a small low-wheeled wooden carriage may be kept for the purpose of transporting them.

Booth's roller was invented by the late George Booth of Allerton, near Liverpool, and comprises five cylindrical pieces, arranged alternately three in one line and two in another, and so constructed on the lever principle that they may be pressed down by weight, and possessing each a diameter of not more than a foot. "Mr. Booth," says Mr. Ransome, "contended for solid rollers of very small diameter, as the most effective in crushing the clods, and throwing the greatest weight on the surface of the ground. From this opinion I venture to differ, believing that whatever advantage may arise from small diameters, it is more than counterbalanced by the difficulty of surmounting clods and other obstacles, and their consequent tendency to drive them before the roller, which would also cause increased labour to the horses."

Spiked rollers are used to reduce the lumps and clods of clay soils. Those of the simplest form consist each of a single wooden cylinder, with spikes of about 3 inches or so in length, inserted quincunxly or in some other regular order; and these perform their work pretty well when the land is dry, but become clogged and inefficient when the land is moist. But the better kinds of spiked rollers have each two cylinders, the one placed before the other, both armed with regular and mutually alternate rows of spikes, and the two adjusted so closely together as to intersect each other's rows of spikes, and in consequence constantly cleanse each other in all their revolutions. One of this class, described in the Leicester Report, has rollers of about 9 inches in diameter, armed with eight rows of spikes, fixed in a frame, mounted on wheels of about $3\frac{1}{2}$ feet in height, and provided with an upright post windlass and power of pullies to raise or lower the rollers at pleasure.

The Earl of Ducie's improved clod-crusher has two parts or lengths in the manner of the common two-cylindered iron roller; but instead of a continuous surface, it has from end to end, round all its circumference, a series of square wrought-iron bars; and it presents the angles of these bars to the clods, so as readily to penetrate and reduce them. It acts well in its proper capacity of a clod-crusher, and at the same time is useful for rolling or pressing wheat in the spring.

Bartlett's cultivator is a roller of 13 thin iron plates of 15 inches in diameter, each fastened to a circular block of wood 4 inches thick, 9 inches in diameter, and bound round with iron,—the plates and the blocks strung together on an iron axle, and made moveable upon it,—and the whole adjusted in roller-style within a strong quadrangular frame, and subtended by a bar with fixed iron scrapers, which keep the roller continually clean. This implement is said to be serviceable in the tillage of wet lands in the extreme south of England; and it may be made with plates and blocks of other sizes than those which we have named, or those adopted by the inventor.

The double-jointed barley-roller is simply a variety of the common two-cylindered or three-cylindered iron roller; but is so constructed that the parts may revolve at opposite angles,—and may also, for convenience in travelling or for any special purpose in tillage, be placed the one behind the other. Its framing, too, is often so con-

structed with twisted joints, as to make the inner end of one part work behind the end of the other, so that no seam is left between them.

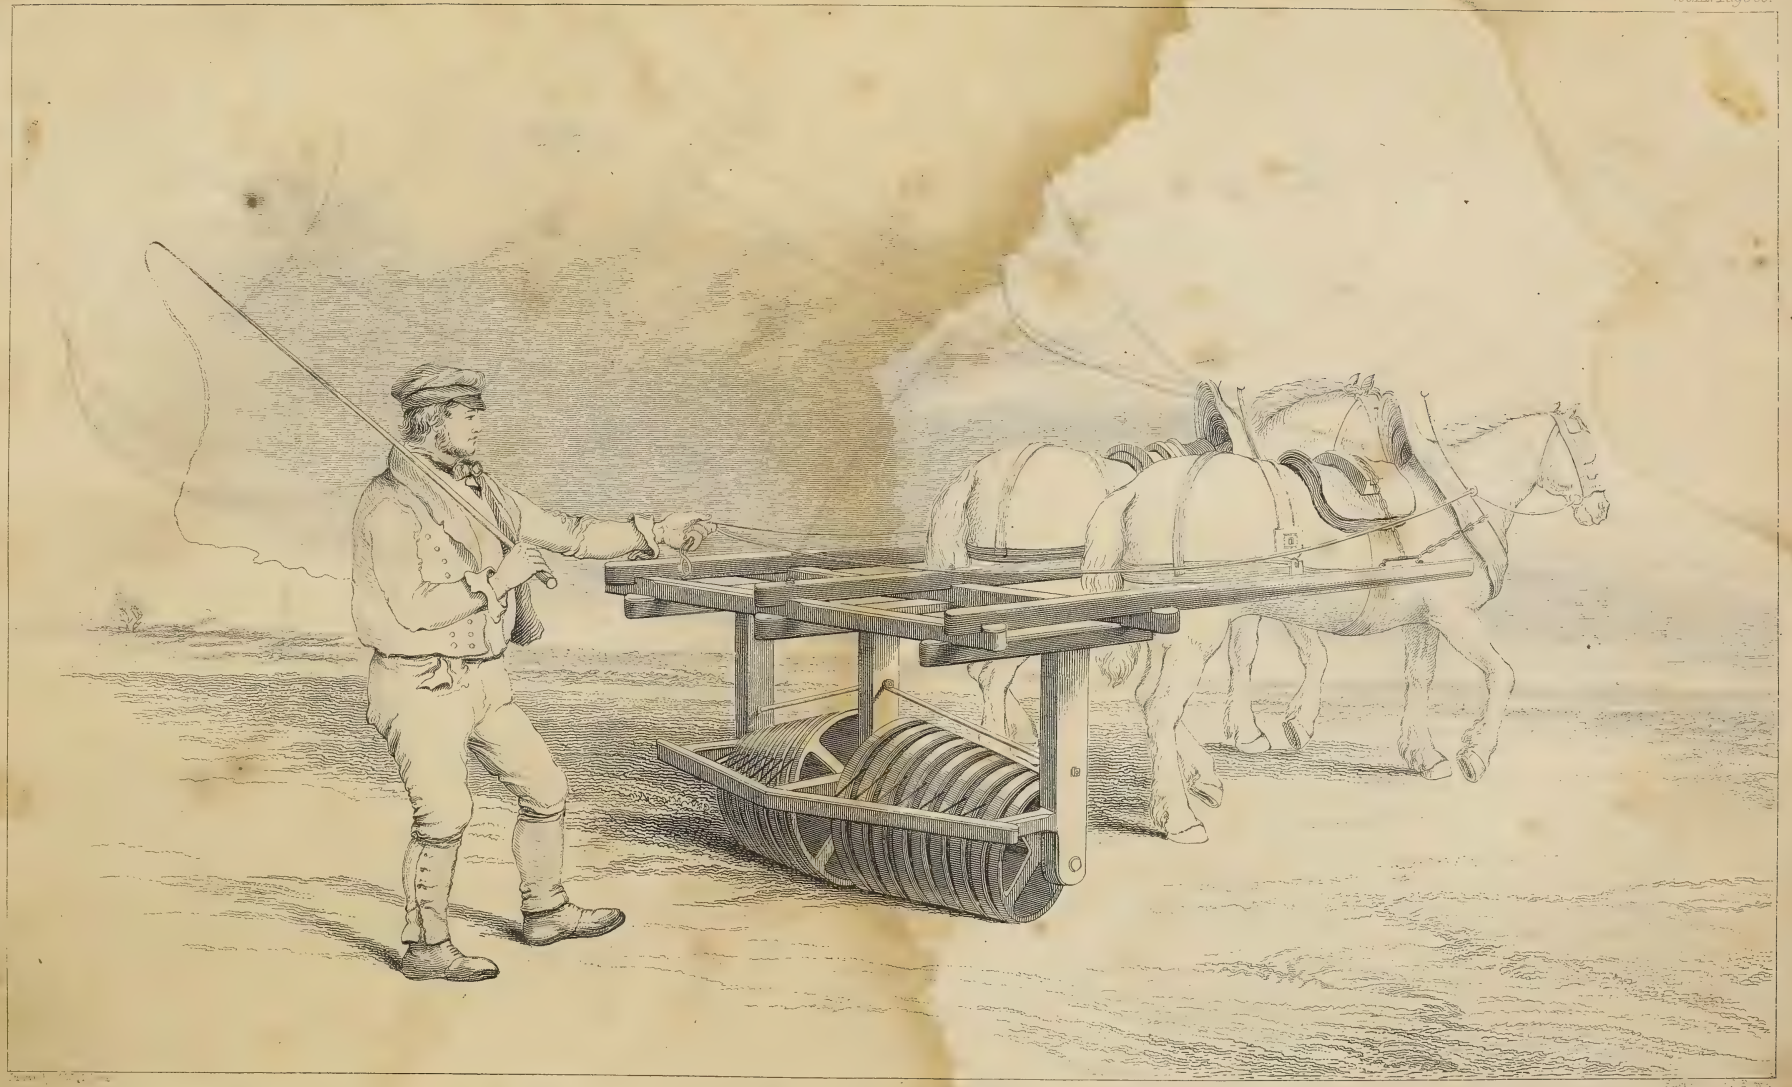
Lord Strathmore's soil-consolidator is a combination of machinery for the purpose of consolidating loose soils. First in it are two common rollers; and these put in motion two wiper shafts; and these lift, in continued rotation, a number of stampers, which are let fall on the soil while the machine is travelling over the surface.

Drill-rollers have a series of stout metallic rings, upon an axis, each commonly about 2½ inches thick, and sometimes so much as 3 feet in diameter; and they are used either without weights for making grooves ready on light soils to receive the seeds of a broadcast sowing, or more or less heavily laden with weights to crush the clods of rough and strong land in the manner of common or of spiked rollers. They have long been known to the farmers of Norfolk and Suffolk, and were a highly appreciated implement so long as 40 years ago; and they have of later years been variously improved,—but principally in rendering each ring independent of the others, so as completely to accommodate their action to diversities of surface, and to facilitate their turning at the end of fields. When a drill-roller is used for crushing clods, it requires to be followed by a harrow of sufficient weight to lighten up the surface; but when it is used for making grooves preparatorily to broadcast sowing, it should not be followed by anything heavier than a fine short-toothed harrow, or even than a mere bush-harrow.

The seam-presser or land-presser or pressure-roller is an abstract of a drill-roller, and has but two double conical wheels for pressing, and is greatly employed in some districts for rolling down the soil newly turned up by the plough, or for closing the furrow-seams of a seed-furrow from lea. The two double conical wheels are set upon an axle, at about 10 inches apart, and are situated on the one side of the machine-frame; while a common wheel supports the other end of the axle, and occupies the corresponding side of the frame. The machine, in working, follows in the wake of two ploughs; its conical wheels run in the seams of the last turned-up furrows; and its common wheel runs upon the unploughed land. It acts more effectually than the drill-roller, and directs its whole force upon each furrow, and gives a firmer bottom for the germination of the seeds, and tends to retard, if it does not altogether prevent, the insidious operations of the wire-worm.

The conical grooved pulverizing land-roller, was invented by J. Stewart Hepburn, Esq., of Colquhalzie in Perthshire; and is described and figured in the 11th volume of the Highland Society's Transactions. It comprises three varieties, and has, as its chief characteristic features, a conically diminishing instead of a cylindrical form of roller, and a series of transverse parallel flutings round the roller's surface. Two of the rollers or conical frusta are adjusted in one frame, base to base, and have their axes so inclined that both the fore-part of their peripheries and the parts in contact with the ground are always in a straight line. The frame is the same as that of a common roller; and three perpendicular bars from it carry the axes of the two rollers; and a light horizontal frame with scrapers is adjusted behind the rollers to clear the grooves of the rollers when at work from all adhering soil. "The effects of such a form of roller upon the surface of the soil," remarks Mr. Slight, "are peculiar and important. While the cylindrical smooth roller acts merely by its pressure on the rough soil intended to be pulverized, one of a conical form, arranged in the manner of Mr. Hepburn's, will, besides acting by its direct pressure, produce a strictly pulverizing effect, by reason of its form; for the cones having a constant tendency to move outward in a circle, but being restrained by the bearings in which they revolve, their surface will produce a crushing and abrading action well adapted to the pulverization of the soil." *Plate LI.*

Crosskill's patent clod crusher is, in several respects, a remarkable and very valuable implement, and was pronounced by the judges to be, with its latest improvement, the most beneficial implement used in agriculture exhibited at the Newcastle Meeting of the Royal Agricultural Society in 1846. "Mr. Crosskill," says the official Report of that Meeting by Mr. Parkes, "about the year 1832 imagined the form of this roller. His first plan consisted in forming a barrel, by stringing a number of narrow indented rims or discs loosely upon a square axis, the whole revolving, together with the axis, in the journals of the frame. In addition to the saw-like teeth into which the periphery of each rim was divided, other teeth were formed, projecting sideways from the plane of the rim, and in a radial line from the centre, so as to leave no portion of the soil unoperated upon. This roller gradually fought its way into considerable practice, being found to effect a much greater amount of superficial pulverization than the common plain roller. Extended experience disclosed other uses than mere clod-crushing, to which it was applicable; and at the same time pointed out defects which deteriorated its performance and diminished its value. The rolling of young wheat and spring corn, or other plants, was commenced with it, and usefully; but it was found that, on turning short at the headlands, injury was done by tearing up the soil in the act of turning. A greater scope for turning than is convenient was, therefore, necessary to avoid this evil. Another evil resulted when using it on soils at all damp or sticky, from the adhesion of earth to the teeth and their interstices, which further limited its useful employment. Mr. Crosskill, observing these defects, applied himself to their remedy,



A Fullarton, & Co. London & Edinburgh

A.Fullarton & Co. London & Edinburgh

and in 1842 he took out a patent for the present implement, the improvements consisting, first, in setting each toothed rim free to revolve separately on a round, instead of their being fitted on a square axle ; and secondly, in giving a different form and direction to the lateral teeth. By the first-named alteration the independent action of each rim was secured, so that each rim, in the progressive movement of the whole series, revolves upon its axis, and at the rate exactly due to the space to be travelled over in surmounting the irregularities presented to it ; whilst in turning, all tearing of the soil or plants is avoided by the same faculty, which permits every rim or disc to adapt its velocity to the space required for each one to pass over, either forwards or backwards, in the act of turning ; in fact, this roller can be turned about on the centre of its axle without producing any injurious effect. The independent motion of the rims also provided a powerful means of self-cleaning ; for, inasmuch as the velocity of the several rims is perpetually varying, so they rub off the soil which might otherwise adhere to them—an action now further increased by enlarging the bore of the eye of each alternate ring, which causes a kind of eccentric or up and down motion to take place between each pair, and among the whole series of rings or discs. This last improvement consists in the enlargement of the eye of each alternate ring, forming collectively the series of rings or discs of which the roller is composed ; so that of these rings, which are 23 in number, 12 have eyes fitting the axle just freely enough to revolve upon it, whilst the 11 alternate rings have their eyes enlarged about half an inch more in diameter. This arrangement has added materially to the effect of the implement in abrading and reducing hard clods ; it has also induced among the rings a more efficient self-cleaning movement, when the roller is used on moister soils or softer clods ; so that, practically, the scope and power of the roller have been augmented, without adding to its cost, or impairing its extreme simplicity ; and it can now be employed on soil when in states which would have clogged it, or have diminished its effect if all the rings on the axis had eyes of similar size. The superior results arising from this disposition of parts are altogether attributable to what is properly termed action — mechanical action ; and it has been owing to its possessing this function in so high a degree, that Mr. Crosskill's patent-roller has proved to be more effective in comminuting and compressing soil than the common plain roller, or than the serrate-edged ringed-roller with a square axle, first introduced by him. Mr. Crosskill's square-axle toothed roller first made its appearance in the Society's show-yard at Cambridge in 1840—the round axled patented machine at Derby in 1843—a premium of £20 was awarded for it by the judges at Southampton in 1844—and it gained the Society's prize of £10 at Shrewsbury in 1845, having on all occasions of trial at the Society's shows greatly excelled the performance of every other roller brought into competition with it. The fourth volume of the Royal Agricultural Society's Journal contains a large collection of instances of its utility in arresting the ravages of the wire-worm—an effect owing probably to the forcible bite of the teeth on the ground—in the pulverization of stiff, and compression of light soils, together with the opinions of numerous agriculturists upon its value as a roller of various crops in a state of young growth. Its application to the latter purpose has greatly extended since that period, and the writer may bear his testimony to the success attending its employment on pasture land in destroying the white slug, curing mossiness, and especially in consolidating soft grass-land after drainage. For these latter uses the effect of the implement is greatly enhanced by weighting it to the full extent of the power of the team which can be commanded." See the article Rolling.

Garrett's patent clod-crusher and cultivator has also a heavy, rough, biting surfaced cylinder, and comprises a patent improved method of heightening or lowering the wood carriage wheels, so as to produce any required degree of pressure in working, and to obviate all difficulty in removing the implement from field to field. This roller acts very powerfully in crushing clods on heavy lands ; and is peculiarly suitable after a drought, or in a very dried state of the soil, for preparing fallow lands for root crops, and for pulverizing hard and cohesive cloddy surfaces, and raising mould for the barley seed. Some very experienced agriculturists who have tried it recommend it as most desirable for preparing clover lands for wheat, by rolling it once or twice over the ploughed and dried land, in order that it may thoroughly press down the flag, and raise an inch or more of mould on the top ; for when the implement is so set upon the travelling-wheels as to enter the ground to the depth of 1½ or 2 inches, it gives that firmness to the under soil which is so desirable for wheat, and presses down the flag so closely as not to admit any harbour for the slug, and at the same time acts as a preventative of the ravages of the wire-worm.

ROLLING. The employment of the roller on gravel walks, on grass lands, on ploughed lands, on sown lands, or on young or rising field crops. Rollers of different kinds, and different weights and sizes, are required for different purposes ; and those of the garden are few and simple, and of easy and obvious application,—while those of the farm are very diversified, and cannot often be used without much judgment respecting the proper time and the suitable circumstances for applying them.

The heavy smooth rolling of pasture lands is highly beneficial under a variety of conditions,—and particularly when the surface has been ren-

dered uneven by the treading of cattle or by the operations of the mole and the ant. The rough rolling of grass lands with Crosskill's roller or with some other of similar action,—followed, however, by a common smooth roller,—is very serviceable in a mossy state of the surface or after the spreading of compost. The smooth rolling of dry absorbent grass land, at an early hour in the morning, when rain has fallen copiously enough to moisten the surface stratum, but not so copiously as to occasion any poaching from horses' feet, is very advantageous for destroying slugs and insects, and for promoting the general health of the sward. The rolling of meadows immediately after the removal of hay is useful for pressing the shed seeds into the soil, and for thickening the next growth of grass.

The rolling of strong ploughed land, in the course of tillage, or in the process of summer-fallow, reduces the most obdurate clods, and powerfully assists the action of the grubber and the harrows, both in co-operating with them to pulverize the soil, and in enabling them to tear out the roots of couch-grass and other destructive weeds. The rolling of light arable land, preparatorily to sowing, renders it comparatively compact and firm, and enables it to retain moisture and to give a good basis to the roots of growing plants, and may occasion it, in a dry season, to yield a very considerably larger crop than it could possibly produce in its naturally loose state. The rough and heavy rolling of cloddy ground, with Crosskill's roller or some similar implement, at a droughty seed-time, makes sure of a sowing season in even the driest weather, and pulverizes into a fine mould such hard and stubborn surfaces as could not possibly be prepared for the seed by any other known process.

The smooth or common rolling of sown lands and rising crops is beneficial in various circumstances and for various ends;—of any crop of grain sown with artificial grasses, for making an even surface, bruising all clods, and pressing down small stones in order to facilitate the future operation of the scythe;—of oats on a light soil, immediately after the seed is sown, unless the ground be so wet as to clog the roller;—of wheat in the spring, after frosts, in order to make the soil lie more closely to the roots of the plants, to encourage vegetation, to strengthen the stems, and to render the grain more perfect;—of drilled turnips, immediately after sowing, in order to make the soil compact, and to promote speedy germination;—of almost all field-crops, in proper conditions of soil, crop, and weather, a little after midnight in order to destroy slugs, snails, and wire-worms and various larvæ, and during the day, in order to destroy the fly or beetle;—and of flax immediately after sowing, in order to make the seeds vegetate equally, and to prevent such after-growths as tend to produce confusion and loss in all the successive stages of the process of preparing and dressing the crop. Rough rolling with Crosskill's roller, besides serving some of these purposes as well as smooth rolling, or better, is suitable for corn 3 or 4 inches out of the ground, on land infested with the grub or the wire-worm, and has been found to save crops which seemed to be threatened with destruction;—for barley or oats or other similar crop, when the plants are 3 inches out of the ground, preparatorily to sowing clover and other small seeds;—for rolling the stubbles of such crop in autumn, in winter, and once or twice in spring when the clover plants have a tendency to be thrown out;—for turnips in the rough leaf, before hoeing, when the plants are attacked by the grub or the wire-worm;—and for drilled potatoes, in order to break and press the ground between the drills, and to give it a harrowed-like surface,—three or four drills being worked at once by taking off the requisite number of roller-parts and inserting iron-bushes in the spaces, so that no roller-parts impinge on the drills to injure the plants.

ROMERIA. A small genus of ornamental, herbaceous plants, of the poppy family. The hybrid species, *R. hybridum*—ranked by Linnæus as a celandine—is an annual indigen of the hedges of some parts of Britain, about two feet in height, and carrying purple flowers in May and June. The refracted species, *R. refracta*, is a hardy annual of about a foot in height, introduced to Britain about 30 years ago from Tauria, and carrying violet coloured flowers about midsummer.

RONDELETIA. A genus of ornamental, tropical, evergreen shrubs, of the madder order. About a dozen species, varying in height from 2 to 15 feet, and chiefly carrying either white or red flowers, and loving a soil of sandy peat, have been introduced to the hothouses of Britain; and about 20 more are known. The earliest introduced species, *R. americana*, brought from the West Indies about the middle of last century, may serve as a sufficient specimen of the whole. Its stem rises 10 or 12 feet high, and ramifies on all sides; its branches are covered with a smooth greenish bark, and garnished with very close-setting foliage; its leaves are alternate, oblong, acute, entire, lucid green above, pale green below, and a little crumpled on their surface; and its flowers come out in bunches at the end of the branches, and are white and have little odour, and bloom in August.

ROOD. See Acre.

ROOF. See Farm-Buildings, Barn, and Cottage.

ROOSTING. See Poultry.

ROOT. The part of a plant which strikes downward or inward into the soil or other sources of the saline principles of vegetable nutrition. It directs its course downward or inward with a tendency apparently as invariable and stubborn as the force of gravitation; it does not carry

branches or leaves or scales in the manner of a stem; it never becomes green in its tissue by exposure to the action of air and light; and it comprises all the points of the plant's basal attachment, and also all the bibulous organs of the plant's functions of nourishment. See the article Absorption of Plants. Some cryptogams, such as many of the confervæ, have apparently no root whatever; a few cryptogams, such as the truffle, look to be all root; many cryptogams, such as the lichens and the mosses, have rather rostels than roots; some aquatic phænogams, such as the duckweeds, have only such roots or absorbing organs as float in water; many phænogams, such as the tropical orchidaceæ and other epiphytes, have only such roots as live upon trees or other plants; and some phænogams, such as many plants of the iris order,—and also some cryptogams, such as some of the ferns,—have roots more or less of the character of prostrate, thickened, underground stems. But all other plants, comprising the enormous majority of all the known flora of the world, and absolutely all which have a comparatively perfect or well-developed phænogamous character, possess true roots, or basal, compound organs of attachment and nourishment, such as we have defined. Yet these true roots present a wondrous diversity of structure and constitution and habits; and might be discussed through a long series of sections, investigating their resemblances and differences and characters and myriads of most beautiful adaptations; but, in the very limited space which we can allow to them, we must simply say, that they are usually classified into the fibrous, the bitten, the spindle-shaped, the bulbous, and the tuberous.

"In all cases," remarks Dr. Madden, "an obvious relation may be perceived between the form of the root and the kind of soil in which the plant grows. Thus, if two specimens of the same plant—some of the grasses, for example—be found growing, the one in clayey, the other in a sandy soil, it will be seen on examination, that the root of the one growing in the sand is much more minutely subdivided, and contains many more small fibres, than the one which grew in clay; and the reason of this is obvious: the spongioles are the only absorbent parts of the root,—they exist only at the extremities of the smallest fibres,—and moreover, they can take up nothing but what is presented to them in the form of solution. Now, in the clayey soil, from its retentive nature, the soluble parts are not allowed to drain away; and hence the plant is supplied with food near at hand, and, consequently, a few short fibres are sufficient. On the other hand, plants growing in sand are frequently deprived of all fluid near them, by the sinking of the soluble matters through the loosely aggregated soil; in which case the plant would inevitably perish from starvation, were it not for the wise law of Nature, which provides against such calamities, by endowing the roots of the plants, placed under such circumstances, with the power of shooting forth innumerable minute fibres in all directions, in order that advantage may be taken of every drop of moisture which falls in their neighbourhood. Nor is it merely in the number of minute fibres that the roots of plants growing in sand differ from those which inhabit the stiffer soils. The form of the body of the root is distinct; thus, nearly all bulbous, and other large succulent roots—as the turnip, for example—require sandy soil; and, moreover, some plants,—as the meadow cat's tail, or Timothy-grass, *Phleum pratense*,—change the form of the root, according to the soil they inhabit; thus, in stiff clays, the plant just mentioned has a fibrous root, whereas in sand it becomes bulbous, and assumes all the characters of *Phleum nodosum*. The explanation here is as evident as in the former case. The bulbs of the roots act as reservoirs of food for the plant; thus, in very dry seasons, these bulbs shrivel up, their fluids being all needed by the rest of the plant, and hence withdrawn. So beautifully do we perceive in this, as in all other cases, that design and adaptation of means to specific purposes, which must impress even the most sceptical with the absolute existence of a Great First Cause."

"But what gives roots their chief interest to the agriculturist," remarks Mr. J. G. Macvicar, "is the fact, that the cellular tissue, of which they are composed, is capable of becoming a reservoir of nutritious matter, which, though naturally designed for the subsequent use of the plant, man and other animals find it convenient to consume. It does not appear that sap is fit for nourishing a plant until it has been elaborated in the leaves; but it frequently happens that more can be elaborated by them at one time than is necessary for the plant's immediate consumption, in which case it is conveyed back, and stored up for future consumption, at a season when the leaves not being in a state of activity, or the soil being exhausted, there is some objection to the immediate formation of nutrient matter. In perennial plants, which form buds, this nutrient matter is usually deposited in the cellular tissue, about their roots or origin, and, when robbed by man, yields sago, and other nutritious articles of diet. When the plant is of that more perfect kind where many buds are formed, and the stem contains a decided pith, in it the nutrient grains and juices are stored, to be carried forward another season to the unevolved bud, by the ascending sap, giving it the characters of elaborated sap, and thus rendering it fit for nourishing the young leaves. But although trees, shrubs, and many forms of plants admit of this supplementary nutriment being deposited, in many little magazines, at the base of the buds,—and though the palms, and the plants which yield sago, admit of its being in one great mass, at elevations in the atmosphere,

—many other plants are of such a structure as to admit of its being deposited only near the ground, or in what we commonly call the root; and it is for the sake of this reservoir of nourishment that the farmer cultivates many crops in his fields. Just as he keeps bees in his garden, for the sake of the honey which they store up for the winter season, he keeps turnips, carrots, mangold-worzel, parsnips, and all his root crops, which have the foliage growing out of their mass in his fields, for the sake of the nourishment which they store up for the fructifying season. It will be seen, then, how much the value of such a crop depends on its obtaining from the soil a plentiful supply of nourishment; and since it is not deposited until the sap has been elaborated by the leaves, it is equally evident how conducive a healthy foliage, warmth, sunshine, and whatever is necessary to their healthy action, is to the formation of a good root. The same view enables us to understand the loss of value which a root sustains when the plant is allowed to run to seed. The nourishment is stored up chiefly for consumption at this critical period, when an exhausted soil, and an advanced season, seem to render precarious the accomplishment of that object which nature is at all times fully bent to perform, before the death of the individual. By this beautiful provision, however, the process of fructification goes on almost independent of accidental circumstances, and even though the plant be torn out of the soil; but, when this all-important end is completed, he who would now seek for nourishment in the root, will find only a husk. Nature is liberal in this, that she makes use of unconscious beings to procure food for sentient beings; but, if these sentient beings do not take the food when it is offered them, so great is her economy that she will cause the unconscious ones to devour it, that nothing may be lost. Thus, it will be seen that both meat and morality may be extracted from a turnip."

ROPE. A series of small fibres united together by twisting or spinning, which unites the fibres together, thus causing them all to act at the same time, and thereby increases the general strength; for if one fibre is weaker than another, or weaker in one part of its length than in another, it derives strength and support from the other fibres that are contiguous to it. On examining the different fibrous materials in common use according to their diameters, silk is decidedly the strongest, and flax, hemp, cotton, and other vegetable matters follow in succession. Silk and flax are too expensive to be used on a large scale, and cotton is too weak; therefore hemp is the material generally resorted to in Europe for making ropes; but different countries adopt such materials as are most convenient to themselves. Accordingly all the ropes that are used in South America and Mexico are made from the fibres of the aloe. The rigging and ropes of the native East India shipping are made from the fibrous external coat of the cocoa nut. A great deal of the rope used in the United States is called *grass rope*, which is believed to be the fibre of the *yucca*. In fact, almost any tall vegetable that possesses great strength of fibre, may be manufactured into ropes. The Society for the Encouragement of Arts, &c. in London, have paid particular attention to this subject, and by consulting the different annual volumes of their Transactions, it will be found that fine and strong thread and cloth may be obtained from the stems of the common stinging nettle and the bean, and that a coarse and strong material is yielded by the stalks of the hop plant, the bark of the lime tree, and several other vegetable productions. The value of these several materials depends, however, upon their strength and durability, and the changes that they undergo by being wet and dry, bent or straight, and under other casual circumstances; and after a fair trial and investigation of their several properties, good hemp appears superior to all that have so far been experimented upon. One of its valuable properties is that its strength is not impaired by sudden bending, while if the aloe or grass rope are so treated, as in tying a knot, they lose their strength very considerably, unless previously steeped in water; and even then, are not so strong in the bent as in the straight parts. As hemp is the best known material, and has been more experimented upon than any other, we shall confine ourselves in the few observations to be made on this subject, to ropes of this material.

When a number of small fibres are united together by the process of twisting or spinning, the thread so produced, whatever may be the material, is called a *yarn*. Yarns may be made large or small, according to the purpose they are intended for. Thus all the varieties of sewing thread, however fine they may be, consist of at least two yarns spun or twisted together. But for rope-making the yarn is much larger, and is generally about $\frac{1}{8}$th of an inch in diameter. In the British navy-yards, the size of hemp yarn is determined by its strength, for each separate yarn must be capable of supporting one hundred weight, and will therefore be a little more or less in diameter, according to the goodness of the hemp. A rope is composed of a number of these yarns, usually from 16 to 25, twisted together, and this in large ropes is called a *strand*. Large ropes are never made immediately from the yarns, but by twisting two or more of these strands together. In the language of rope-makers, three strands united, form a *hawser;* but when four are used, the rope is called a *shroud*. A *cable* is the union of three hawsers or three shrouds, and this large process of spinning is called *laying* a rope. By unravelling the end of a rope, the number of its component yarns may be readily discovered and counted, and as each yarn should bear 1 cwt., it may seem that this would offer a ready means of ascertaining the strength of new ropes. But the very formation of a rope renders this impossible. If the fibres ran in right lined directions from end to end of the rope, it would give a near approximation to truth; but the twisting of the fibres together makes the action an oblique, instead of a direct one; and thus, as those fibres near the centre of the rope, take a much straighter di-

rection than those on its outside, all the violence of the strain will fall upon the central lines of fibres, while those on the outside will scarcely feel it at all. Taking the sum of the fibres or yarns, therefore, will give no clue to the strength of a rope as they are usually made; and no rope so made can possess a strength anything like equal to what the sum of the yarns would produce or support if they could act singly. The late Captain James Huddart, of the British East India company's service, contemplating the imperfections to which large ropes were liable, from unequal or imperfect twisting, and the unequal strain to which the individual yarns were exposed in their common arrangement, invented a most admirable and simple contrivance which he called a regulator, and for which he obtained a patent, by means of which different quantities of yarn was supplied to the different parts of the strand while it was twisting or laying. That yarn that went to form the centre of the strand, never deviated from its right lined direction, while a larger quantity was given out to the outsides which had to pass obliquely, and consequently through more space, and by this means, and using a less hard twist than had formerly been resorted to, he produced the most perfect and uniform ropes, which were so perfect as to the equilibrium of their own parts, that they had no tendency to twist or recoil even when quite new; and on subjecting his ropes to experiment, it was found that instead of losing any of the original individual strength of the fibres, they assisted each other, and produced an aggregate power greater than their primitive one. Since the expiration of his patent, some of the principal rope-makers have adopted his plan of working, the advantages of which soon became known among nautical men.

The tarring of ropes can evidently add nothing to the absolute strength of the materials of which they are formed; and yet it is thought to render ropes stronger. If it does so, it can be on no other principle than that the tar cements the fibres together, and thus causes those parts to act conjointly, which without such assistance might have acted separately. The great use of tar is, however, to exclude moisture and prevent the rope from rotting, which it would do in damp situations; and it likewise prevents sand and grit getting into the inside of a rope, and these are very detrimental to ropes that are kept in constant motion, as they fret and wear away the internal fibres.

The rule that has been established by practice for ascertaining the strength of *new* ropes made of the best hemp, without tar, is that they should support one-fourth of the square of their circumference taken in inches, in tons. Thus, if a rope is $2\frac{3}{4}$ inches in diameter, its circumference may be taken at 9 inches, the square of which is 81 inches, and dividing this by 4, the quotient would be $20\frac{1}{4}$ tons, which such a rope should bear upon a fair and even strain; but as all ropes are subject to jerks and concussions, it is better to take a fifth instead of a fourth of the square of the circumference, and this would reduce the above named rope to $16\frac{1}{5}$ tons. Moreover as this rule applies to new ropes, made of the best material, and much inferior hemp is used, or cheaper materials of less strength are almost constantly mixed with it, and a rope is expected to last and wear a considerable time; so it is not prudent to put more than half this load upon a rope that is in constant use, because if strained to its full extent in the first instance, it will soon give way by use. The rule which Captain Huddart established in his rope manufactory, and upon which he would warrant all ropes made there, was to multiply the square of the circumference of the rope by 900, and this would give the number of pounds avoirdupois which the rope would sustain with safety. If we take the same example as before, of a rope having 9 inches circumference, then $9^2 = 81 \times 900 = 32\frac{1}{2}$ tons, or rather better than a third more than a rope of ordinary formation would bear.

M. Du Hamel states that tarred rope is much weaker than that which is untarred, their diameters being equal, and he gives a table of comparative experiments made with three inch rope in proof of this assertion, in which the tarred rope is in every instance greatly inferior in strength to that without tar, but he assigns no reason for this apparent phenomenon, although it is well understood by every rope-maker. They usually demand the same price for tarred rope as for that which is clean, and even sometimes make a favour of charging nothing for the tar and trouble of applying it. But the fact is, the tarring is always performed upon the separate yarns, by drawing them through a kettle of boiling tar, before they are twisted into strands. The hot tar swells the fibre, and a quantity of it adheres to each of them, so that the diameter of the yarn becomes sensibly increased, and of course a much less number of yarns become necessary to form a rope of the same diameter, than if clean hemp was used. This is quite sufficient to account for the deficient strength of tarred ropes; but if, instead of comparing the ropes by their diameters, they were compared by the number of yarns they contained, then the tarred rope would, it is believed, have the advantage. The inexperienced purchaser when he buys a tarred rope, does not usually consider that in each pound of rope he buys, he gets about 14 oz. of hemp and 2 oz. of tar, which are both sold for the same price, although hemp is at least sixteen times more costly than tar. M. Du Hamel, however, goes on to state, that it is decided by experience that white cordage in continued service, is one-third more durable than tarred; that it retains its strength much longer while kept in store; and that it resists the ordinary injuries of the weather one-fourth longer. These observations deserve the attention of practical men, being very important. There is, however, a reason why tarred ropes should be used in particular cases, such as the standing rigging of ships, or that which does not require to be run over pullies or to move; such as the main-stays, fore-stays, and shrouds, by which the masts of vessels are held and maintained in their vertical positions. The reason is that all untarred

cordage (particularly when new) is highly hygrometric, and expands and contracts in its length to a great extent by being dry and wet. The damp state constantly producing contraction, and the dry one extension. This contraction by wetting exercises so much force, that if a rope is fully stretched in its dryest state, and then wetted, it will break, or tear away the parts to which the ends are attached if they are less strong than the rope. If, therefore, a mast was braced in its proper position by dry white ropes, a shower of rain would probably bend the mast or break the ropes. On the contrary, if the mast was braced as tightly as possible by damp ropes, a few hours sunshine would render it quite loose. Anything therefore that will destroy the hygrometric properties of the rope by rendering it less, or not at all absorbent of humidity, will be beneficial in such cases; and tar or paint answers this purpose.

Ropes are always sold and valued by weight, but are described by their circumference in inches. Thus what is called a 3 inch rope would only be about 1 inch in diameter, and when a 24 inch cable is spoken of (being the largest size usually made), a cable less than 8 inches in diameter is understood. See Leather-Bands.

ROPE-GRASS. See Restio.

ROSA. See Rose.

ROSA MARIÆ. See Anastatica.

ROSCOEA. A genus of ornamental, tropical, perennial-rooted, herbaceous plants, of the scitamineous order. Five species, all about a foot high, and carrying purple flowers in July and August, and thriving best in a soil of sandy loam, were introduced to British collections about 28 years ago from Nepaul.

ROSE,—botanically *Rosa*. A large genus of ornamental, calyciflorous shrubs, constituting the type of the natural order Rosaceæ. This order is, in a very considerable degree, identical with the Linnæan class Icosandria; and though of very great extent, and quite naturally distributable into distinct groups or tribes, it possesses remarkable uniformity of botanical character,—insomuch that all its genera, no matter how diverse in habit or how peculiar in general appearance, may be considered as mere proximate and easy variations from the true rose genus. It is at once one of the largest, one of the most magnificent, and one of the most grateful of all the natural orders. It comprises many plants of rich and diversified medicinal virtue,—some plants of considerable utility in the arts,—multitudes of plants of rare beauty and elegance and fragrance,—very many of the most valuable or most ornamental plants of hedges, shrubberies, and pleasure-grounds,—and all the most important fruit-trees and fruit-shrubs of the temperate regions of the world. Eight tribes, and about 50 genera, and nearly 1,000 species of it, besides myriads of varieties of its finest flowering and fruiting plants, at present occur in Britain; and more than three-fifths of all the species are hardy shrubs or hardy trees,—and a good deal more than one-fourth are hardy herbs,—while only about one-ninth require the protection of the greenhouse or the stove. The tribes which contain the greatest number of genera are dryadeæ, sanguisorbeæ, and pomaceæ; two tribes which contain each only one genus are roseæ and neuradeæ; and the other three tribes are amygdaleæ, spiræaceæ, and chrysobalaneæ. Some of the best known or most interesting genera, additional to the true rose genus, are the strawberry, the potentilla, the bramble, and the avens, belonging to the tribe dryadeæ,—the great burnet and the ladies' mantle, belonging to the tribe sanguisorbeæ,—the hawthorn, the medlar, the quince, the cotoneaster, the loquat, and the pear and apple and service, belonging to the tribe pomaceæ,—and the almond, the peach, the apricot, the plum, and the cherry, belonging to the tribe amygdaleæ.

The petals of a rose are five in number; the calyx is pitcher-shaped, five-cleft, fleshy, and contracted in the neck; and the seeds are numerous and hispid. Twenty-two species grow wild in Britain; about 100, or upwards, have been introduced from other countries; and about 40 more are known. Hybrids and varieties of most of the finer species have also been multiplied beyond number. A few of the species, comprising a multitude of varieties, are evergreen shrubs; a few, comprising very many varieties, are either climbing or trailing shrubs; and the vast majority, as well of species as of varieties, are upright deciduous shrubs. One subgenus, represented by the Scotch rose, has equal, numerous, bractless prickles, persistent connivent sepals, and scarcely any disc; another, represented by the Cinnamon rose, is bracteate and unarmed, and has glandless lanceolate leaflets, and a slender disc; a third, represented by the Provence or hundred-leaved rose, has unequal bracteate prickles, rugose leaflets, and a thick disc surrounding the throat; a fourth, represented by the rusty sweet briar, has arched branches, unequal prickles, glandular leaflets, persistent sepals, and a thick disc; a fifth, represented by the dog-rose, has arched branches, equal hooked prickles, glandless leaves, deciduous sepals, and a disc surrounding the throat; a sixth, represented by the villous rose, has erect branches, straight prickles, persistent connivent sepals, and a thick disc surrounding the throat; a seventh, represented by the clustered-styled rose, has its styles joined into a long column, and has also adnate stipules; and four other but very small subgenera, aggregately comprising less than a dozen species, have characters different from all these seven and from one another. But the families into which horticulturists and florists and nurserymen distribute roses amount to upwards of thirty, and comprise only the ornamental sorts, and have little or no reference to

proper botanical characters, and are so fused into one another as to defy the efforts of all but the most studious amateurs to trace them; and some even consist entirely of fancy varieties, and have been grouped, not on any principle of constitution or form or habit, but on the preposterous ground of mere parentage. Even the present botanical classification is difficult to a novice, and has been in a considerable degree stultified and confounded by the multiplication of all sorts of hybrids; and the present horticultural classification is both absurd and bewildering, and has for a long time become increasingly uncertain and unsettled, and not only wants proper characters for its families, but distributes some classes with very distinct natural characters through two or three or even a larger number of its groups. If the properties of climbing and dwarf, of solitary-flowered and bunch-flowered, be adopted as subdivisional characters, four families, the China rose, the double garden rose, the perpetual rose, and the briar-rose, might probably be made to comprise all the eleven hundred varieties or so which at present figure in the best floral catalogues. The China might comprise all the present China, the tea-scented, the miniature, and such of the bunch-flowered or noisette as have smooth wood and continuous growth, and might be subdivided into the climbing, the climbing noisette, the dwarf, and the dwarf noisette; the double garden might comprise all the deciduous kinds, or all the out-of-door summer-blooming sorts, except the perpetual and the moss; the perpetual might comprise the moss-roses, and all the other sorts which send out a succession of blooms till a late period in autumn,—and both this and the double garden might be subdivided in the same manner as the China; and the briar-rose might comprise all the sorts, whether true briars, or Scotch roses, or whatever else, which have short joints, and flower all along the stem, and are perfectly deciduous.—We shall, in the sequel of this article, first notice some of the most remarkable species; next, give a brief general notice or two respecting the finest garden varieties; and next, say something respecting the culture and propagation of the garden varieties.

The dog-rose, *R. canina*, is common in the hedges of Britain, and in most parts of Continental Europe. It is a beautiful wild ornament, and exhales a delicious fragrance. Its stem is smooth, and has pairs of alternate, equal, hooked, bright-red prickles, and sends out elongated, arched, spreading branches, and rises to the height of 8 or 10 feet; its leaves are pinnate, and have each seven leaflets, and stand on glandular, pubescent, prickly footstalks; its leaflets are ovate, pointed, and smooth, and have a shining upper surface and a deeper green under one; its flowers come out on either solitary or corymbose peduncles, and are odorous and either white, or flesh-coloured, or pink, and bloom in June and July; and its fruit is the well-known common hip or hep,—an ovate, smooth, fleshy, red-berry-like calyx, containing about 30 long angular seeds within a loose packing of white, silky, irritating bristles. Some distinct varieties, such as the needle-leaved, the grey, the hill, and the thicket, occur wild in Britain; and some ornamental varieties, such as the Bourbon, Schott's, and the Egyptian, have been introduced from other countries, and are cultivated in gardens. The fruit of the dog-rose has a place in the pharmacopœia, and possesses cooling properties, and is used in the form of a confection. Its sweet, pleasant, acidulous taste depends on sugar and uncombined citric acid.—Six indigenous species, Sherard's, Forster's, the naked, the twiggy, the spriggy, and the bractescent, belong to the same subgenus as the dog-rose; and all these occur in hedges, and have pink flowers, and bloom in June and July,—two of them, the twiggy and the spriggy, have a trailing or procumbent habit, and are one-half or two-thirds as long in the stem as the dog-rose,—and the other four have an upright habit and an average height of about 6 feet. The China roses, the Boursault roses, and the small-leaved roses,—the first introduced from Bengal about 60 years ago, the second originating in a hybrid in 1821, and the third introduced from India in 1823,—also belong to the dog-rose subgenus.

The Scotch rose or spiniest rose, *R. spinosissima*, grows wild on sandy heaths in Scotland, England, and most parts of Continental Europe. Its height is commonly about 2 or 3 feet, but varies with soil and culture and variety; its branches or shoots are numerous, upright, and very prickly or briary, and are smartly set off with beautiful foliage; its leaves are pinnate, and of a fine green colour, and more delicate than those of any other rose; its leaflets are small, and stand along the midrib in the manner of those of the burnet; its flowers come out in great profusion over the whole length of the stems or branches, and are small and of a white and red colour and almost like the flowers of briars, and bloom in June and July; and its fruit or heps have the appearance of black-berries, and are highly ornamental in autumn and winter. Numerous varieties are cultivated in gardens, and look exceedingly pretty in clumps or on a bank, but are not adapted to be grown as standards.—Four indigenous species, and two admired horticultural exotic species, belong to the Scotch-rose or pimpinella-leaved subgenus,—the reddish rose, *R. rubella*, inhabiting the sea-shores of some parts of England, carrying pink flowers in June and July, and including a black-fruited variety,—the eglantine, *R. eglanteria*, commonly about 4 feet high, carrying yellow flowers in May and June, and including one or two wild varieties,—Sabine's rose, *R. Sabini*, inhabiting the woods of various parts of Britain, attaining an average height of about 8 feet, and carrying

white and red flowers in May and June,—Don's rose, *R. Doniana*, inhabiting the hedges of various parts of Britain, attaining an average height of about 4 feet, and carrying pink flowers in May and June,—the alpine rose, *R. alpina*, introduced from Switzerland in the latter part of the 17th century, carrying pink flowers in June and July, and comprising at least a dozen well-defined varieties, differing from one another in height, in colour of flower, in habit, and in other characters,—and the double sulphur rose, *R. sulphurea*, introduced from the Levant in the former part of the 17th century, attaining an average height of about 3 feet, carrying yellow flowers in July, and constituting a beautiful and much-admired object, but remarkable among roses for great shyness and difficulty of cultivation.—The briar-roses, which possess considerable affinity to the Scotch roses, though they constitute a different family in the horticultural classification, and also a distinct subgenus in the botanical arrangement, are noticed in the article Briar (Sweet).

The villous rose or apple rose, *R. villosa*, grows wild in the hedges of various parts of Britain, and in most parts of Continental Europe. Its average height is about 6 feet; its shoots are strong and bold, and have a smooth reddish bark, and readily distinguish it in winter from all other roses; its prickles are thinly placed, and very strong and sharp; its leaves are large and very hairy, and have a downy under-surface; its flowers are red or pink, and bloom in June and July; and its fruit are as large as small apples, and are beset all over with soft prickles, and give the plant a singular appearance, and, when preserved, make a very pleasant sweetmeat.—Four other indigenous species belong to the same subgenus as the villous rose,—the slender, *R. gracilis*, inhabiting highland glens, attaining an average height of about 8 feet, and carrying red flowers in June and July,—and the rougher, the various-leaved, and the downy-leaved, *R. scabriuscula*, *R. heterophylla*, and *R. tomentosa*, all inhabiting hedges, and attaining an ordinary height of about 6 feet, and carrying pink flowers in June and July.—The Irish rose, *R. hibernica*, and the white rose, *R. alba*, also belong to this subgenus,—the former peculiar to Ireland, and inhabiting thickets in that country, and having an ordinary height of about two feet, and carrying pink flowers from June till November,—and the latter introduced to Britain from the Crimea toward the close of the 16th century, and having an ordinary height of about 4 feet, and characterised by green shoots, glaucous green leaves, prickly petioles, hispid peduncles, and smooth, oval germens, and comprising many garden varieties of all colours from pure white to a bright but delicate pink.

The Provence rose or hundred-leaved rose, *R. centifolia*, was introduced to Britain from the South of Europe toward the close of the 16th century. It is the prince of flowers, and has for ages been an universal favourite, and is cultivated in almost every region of the civilized world, and has a place in all sorts of gardens from the poorest to the most magnificent; yet it cannot be certainly traced to its origin,—though it is variously said by some rare ancient and modern writers to grow indigenously in Macedon, in China, and in Northern Persia. It comprises some very distinct varieties, and a great multitude of subvarieties and hybrids; and it may be regarded as having the well-known old cabbage rose as its type. Its stem is branched and bushy and about 3 feet high; its leaves are compound, and have rough footstalks, and comprise each two or three pairs of leaflets, and a terminating odd one, all on very short petioles; its leaflets are broad, oval, smooth, and serrated,—deep green above, hairy below, and purple on the edges; and its flowers are large, and stand on brownish bristly footstalks, and have semi-pinnate calyx segments, and very numerous, extremely fragrant, beautiful, pale red petals, and bloom from June till August. The petals of this rose are distilled with water for yielding the exquisitely odorous attar of roses, one of the richest and most costly perfumes; and they at the same time strongly impregnate the water with their odour, and yield the well-known rose water of perfumers and druggists. The petals are likewise used in medicine; they have a sweetish, subacidulous, and eventually somewhat bitterish taste; they possess slightly laxative properties; and they are made up with sugar into a syrup, which is given along with other gentle aperients to infants. — The moss-rose, and the pompone rose,—the former characterised by the mossy appearance of its peduncle and its calyx, and both comprising many most beautiful subvarieties—are simply varieties of the Provence rose, and botanically bear the names of respectively *R. c. muscosa* and *R. c. pomponia*. But the hybrid Provence roses, constituting a large family in the common horticultural arrangement, are intermediate between the Provence rose and the French rose, and have the dense foliage of the one and the long shoots of the other.

The French rose, *R. gallica*, grows naturally in most parts of Continental Europe, and was introduced to Britain toward the close of the 16th century. It belongs to the same subgenus as the Provence rose. Its stems rise two or three feet high, and are erect and almost destitute of prickles; its leaflets are subacute, and not so large as those of the Provence rose, and scarcely tomentose below; and its flowers are not so double as those of the Provence rose, and have large, widely open, deep rich crimson coloured petals, and bloom in June and July. About two hundred varieties and subvarieties are cultivated in gardens; and they are distributed by some cultivators into two groups,—the one with self-coloured and shaded flowers, and the other with

variegated flowers. The full flower-buds of the French rose are used in medicine, and are extensively raised for medicinal purposes in the vicinity of London. They are less fragrant than the flowers of the Provence rose; but they improve by drying. They have a pleasantly bitter and austere taste; and they yield both their taste and odour to boiling water. They possess astringent and tonic properties; and are pharmaceutically prepared in the forms of infusion, confection, honey, and syrup.

The damask rose, *R. damascena*, belongs also to the same subgenus as the Provence rose and the French, and was introduced to Britain from the Levant 20 or 25 years earlier than either. It has an average height of about 3 feet; and carries pink-coloured flowers in June and July; and is sometimes confounded with the normal Provence rose; and comprises a very great number of garden varieties. The family of the damask rose, however, as usually grouped in catalogues and collections, is one of the most incongruous of all the horticultural families, and comprises not only a wide diversity of colours, such as white, white and red, flesh-coloured, striped, and red-margined, but also the most discrepant characters, and even perfectly contrasted habits.

The musk rose, *R. moschata*, was introduced to Britain from Barbary toward the close of the 16th century. It is an evergreen, and belongs to the clustered-styled subgenus, and has long been a great and general favourite. It is naturally a trailing or a climbing plant of about 12 feet in length; but, when planted singly, it forms itself into an erect bush of 5 or 6 feet in height. Its stems are clothed with a green bark, and armed with strong, crooked, white spines; its leaves are five-lobed, smooth, and lucid green, and make a fine appearance in winter; its lobes or leaflets have acute points, and are slightly sawed on their edges; and its flowers come out in large bunches at the end of the branches, and are white, and have a strong musky odour, and bloom from July till October. A few varieties of it of very distinct character occur in gardens, some evergreen and others deciduous,—some not more than 4 feet high, and one so much as 30 feet high; but the family of musk roses, in the common horticultural arrangement, partakes largely of the uncertainty and confusion which prevail so generally through that arrangement.—Two indigenous species, the clustered-styled rose, *R. systyla*, and the corn white dog rose, *R. arvensis*, belong to the same subgenus as the musk rose,—both inhabiting the hedges of various parts of Britain,—the former about 6 feet high and carrying pink flowers from May till July,—and the latter about 8 feet high and carrying white flowers in June and July.

The garden rose is the only flower which is beautiful in all its stages, from the instant of its incipiently bursting the calyx till it attains full bloom; it is also the only flower which is really rich in its confusion, or which is not the less elegant for the total absence of all uniformity and order; it likewise possesses points or developments which rank as excellencies in one group and as blemishes in another; and it therefore is more difficult of definition than any other florist's flower. Yet some very distinct properties can be named as essential to goodness in all roses whatever; and other and additional ones, as essential to all the varieties of each of some of the principal groups.—As to all roses whatever,—1. The petals should be thick, broad, and smooth at the edges. Whether this be for a moss, which is never to be shown fully opened, or the florist's favourite, which is to be shown as a dahlia, this property is equally valuable, because the thicker the petal the longer it is in opening, and the longer does it continue in perfection when it is opened. The thicker the petal, too, the more dense and decided the shade or colour, or the more pure a white; while the most brilliant scarlet would look tame and watery if the petal were thin, transparent, and flimsy. 2. The flower should be highly perfumed. Whether the plant climb the front of a house, or bloom on the ground, or mount poles or other devices, fragrance is one of the great charms which place the rose on the throne of the garden as the queen of flowers. 3. The flower should be double to the centre, high on the crown, round in the outline, and regular in the disposition of the petals The more double the flower, even when amounting to confusion, the more full and beautiful the bud in all its stages. Those who have noticed the single and semi-double moss-roses will remember that the buds are thin and pointed, and starved-looking affairs, while the old common moss-rose, which is large and double as the cabbage-rose, is bold, full, rich, and effective, from the instant the calyx bursts.—As to every moss-rose, the quantity of moss, the length of the spines which form it, and its thickness or closeness on the stems, leaves, and calyx, cannot be too great; the length of the divisions of the calyx, and the ramifications at the end, cannot be too great; the plant should be bushy, the foliage strong, the flowers abundant and not crowded, and the bloom well out of the foliage; the colour should be bright or dense, as the case may be, and must be the same at the back as the front of the petals; and the stem should be strong and elastic, and the footstalks stiff, so as to hold the flower well up to view.—As to all roses for stands, designed to be set out in detached flowers like dahlias, the petals should be imbricated and in distinct rows, whether they be reflexed, like some of the velvety tuscan kind, or cupped like a ranunculus, and the petals to the centre should continue the same form, and only be reduced in size; the colour should be distinct and new, and stand fast against the sun and air, till the bloom fail; the stem should be strong, the footstalk stiff and elastic, the blooms well out beyond the foliage, and not in each other's way. The very worst habit a rose can have is that of throwing up several blooms close together, on short stiff footstalks, some of which must be cut away before the others can be fully developed; as show-flowers they are bad, and as plants they are very untidy; the side buds prevent the centre flowers from opening circularly, and when the first beauty is off them, they exhibit dead roses held fast between two living ones.—As to all noisette roses, the cluster should be sufficiently open to enable all the flowers to bloom freely, and the stems and footstalk should be firm and elastic, to hold the flower face upward, or face outward, and not to hang down, and show the outside, instead of the inside of the blooms; the bloom should be abundant at the end of every shoot; the blooming shoots should not exceed twelve inches before they flower; the bloom should stand

out beyond the foliage; and the plant should be compact and bushy.—And as to climbing roses, the joints should be short from leaf to leaf; the blooms should come on very short branches, and all up the main shoots; the plant should be always growing and developing its flowers from spring to autumn; and the foliage should completely hide all the stems, whether the plant be on front of a house or on any given device.

Some of the horticultural families have hardly a good rose among them; and others have far fewer good ones than bad. In fact, nine-tenths or so of the varieties enumerated in catalogues are not worth possessing, either on account of their intrinsically bad properties, or because two or three or more of them are so closely like one another as to be practically one. Mr. Rivers gives upwards of a thousand professedly select varieties in thirty-three families, and makes out of this great multitude a selection of six of the largest, six of the sweetest, six of the most brilliant, six of the strongest, six of the finest shaped, six of the earliest small, six of the earliest large, and six of the latest; and this selection is probably the best guide which a purchaser can follow, if not to actual varieties, at least to groups and numbers. The six largest are La Reine, rosy pink,—William Jesse, light crimson tinged with lilac,—Souvenir de la Malmaison, pale-fleshed tinted with fawn,—Calypso, pale rose,—Brennus, bright red,—and Chenédolé, vivid crimson; and these comprise two perpetual, one Bourbon, two hybrid China, and one which partakes much of the character of a hybrid Chinese. The six sweetest or most fragrant are Riego, a sweet briar,—Crested Provence, an ordinary rose colour,—the common Cabbage-rose, an old favourite,—the common Moss-rose, also a universal favourite,—Crimson Perpetual, bright crimson,—and Prince Albert, purplish crimson; and these six comprise no less than four families—one being a perpetual, one a hybrid perpetual, one a hybrid sweet briar, two Provence, and one moss. The six most brilliant are Vesta, a very old variety,—Rouge Eblouissante, or Assemblage des Beautés,—Eblouissante de Lequeue,—Feu Brilliante,—Grande Capitaine,—and Gloire de Rosamène; and four of these belong to the family of Rosa Gallica, and two to the family of Bourbon. The six strongest or most vigorous growing are Great Western, deep reddish crimson,—Hortensia, bright pink,—Charles Duval, bright rose,—Paul Perras, brilliant shaded rose,—Elise Mercœur, rose colour with red centre,—and Chenédolé, already noticed in the first six; and here we have five hybrid Bourbons, so called, and one hybrid China. The six finest shaped are Triomphe de Jaussens, brilliant crimson,—Kean, nearly scarlet,—Coupe d'Hébé, delicate rose colour, often shaded with pink,—La Volupte, deep rose,—Rose Devigne, a delicate pink,—and Boula de Nanteuil, crimson purple. The six earliest small are Spong's Rose, bright rose colour,—Rose de Meaux, an old acquaintance,—mossy Rose de Meaux, or Pompone, beautifully mossed,—Persian Yellow, bright gold colour,—Chinese Sweet-briar, bright pink rose,—and Burgundy, an old dwarf rose. The six earliest large are George the Fourth, Ne Plus Ultra, Fulgens, Blairii No. 2, Magna Rosa, and Triomphe d'Angiers,—all hybrid China roses. And the six latest are Madame Laffay, rosy crimson,—Lady Alice Peel, deep pink,—Baronne Prevost, rosy blush,—Doctor Marx, rosy carmine,—Duchess of Sutherland, bright rosy blush,—and Mrs. Elliott, light crimson tinted with lilac; and all these are perpetuals, or hybrid perpetuals.

The proper soil for the rose is strong rich loam, and either well decayed vegetable mould, or cow-dung or horse-dung. If the soil be light, holes must be dug, and loam and dung forked in; for troublesome as this may be, it is the only way to secure a good growth and bloom. Among the evils of poor soil, it is not the least that it frequently makes the flower that would otherwise be double come single or semi-double, so as to destroy all identity of the variety by its bloom; and although many thousands of roses not worth a penny have been sent out, many others thoroughly good have been condemned, because the party growing them knew nothing about their cultivation, and starved them into a false character. "The rose, perhaps, more than any other ornamental shrub," remarks Mr Rivers, "requires constant culture to make it bloom in perfection, unless in the most favourable rose soils. Roses require to be removed, and to have their roots trimmed, every third year. When taken up, these roots will be found to have lost most of their fibres; but, naked as they are, if they are then trimmed, the branches thinned and shortened, and plenty of well-rotted manure mixed with the soil they are planted in, the plants will be quite renovated, and bloom as fine, and often finer, than young plants. This treatment, perhaps, is most applicable to standard roses. With dwarfs the trouble is too much, unless with the choicest sorts, as they are sold at such low prices, that it would be cheaper to make a new plantation. In very clayey cold soils, the finest compost possible for roses is well-rotted dung and common-pit sand, not road sand, equal parts. When standards are removed, they ought to have their heads thinned, and shoots shortened early in spring. A mistaken notion, which I often find current, is, that they ought to push, that is, begin to shoot, before the branches are shortened; this has sealed the doom of very many standard roses. I have an idea that standard China roses, of the most choice varieties, with stems from 3 to 4 feet, might be made highly ornamental summer plants. They are too tender to endure the ordinary severities of our winters as standards; but if taken up every autumn, put into large pots, and placed in a dry shed, they would remove into their summer quarters in the spring with perfect safety, and bloom much finer than if exposed during winter, and their shoots injured by the severity of the weather. The varieties of *Rosa indica odorata* bloom exceedingly well in this manner, as do all the strong-growing varieties of China roses. *Rosa Grevillii* and *multiflora* also form curious objects, and bloom very freely, when grown as standards. The hardy climbing roses, and several of the climbing China roses, form fine objects when trained *en pyramide*, that is, in the French manner of training pear trees; but when trained in this manner, as climbing roses do not form a stem strong enough to support themselves, the strong central shoots must be tied to iron or wooden stakes, and the side shoots from them shortened every season; in this manner, with proper culture, they will form pillars of roses, from 6 to 10 feet in height. * * * Standard roses always appear to me to have the prettiest effect when budded on neat stems, varying from 1 foot to 4 feet in height; they are more easily removed, are nearer to the eye, and their perfume is more readily inhaled. They will soon get over the habit of throwing up suckers, which with some is an objection, if care is taken when they are removed, to disbud the lower part of the stem, and to take off those roots which seem to have a tendency to throw up suckers. When thus treated, they form pretty compact heads, and yet not lumpish, if properly pruned. A prejudice is often found to exist against budded roses, and this has arisen principally on account of improper stocks being used. Most decidedly, roses never bloom so finely as when budded, and the most proper and durable stock is *Rosa canina* with its varieties; while *Rosa arvensis* is, perhaps, the worst."

The China rose, and all the short-jointed, smooth-

barked kinds that are like them in habit, will strike, bud, graft, grow and bloom, any month in the year. The only thing necessary, is to have plants in all stages, and there will never be any want of flowers. In the greenhouse they continue growing on, and blooming at all times; but they cannot be kept too cool generally, and if abundance of flower is required on a plant, it must have a previous rest, and shift to a warm temperature, and if matted in the roots, a large pot, and the heat gradually increased until it will bear that of a moderate stove. All the new young growth will flower about the same time, or at least sufficient of it to well decorate the plant. Cuttings may be struck in the spring, planted out in beds, six inches apart, to grow a little; the tops be pinched off, and the buds taken away all the summer, to make them bushy; and they may be potted up into forty-eight sized pots, half loam, a fourth peat, and a fourth cow dung; trimmed a little into shape, and placed in the shade a while. In September they may be put into their frames, covered up at night against frosts, and opened in mild weather, until the middle of November; they may then be removed, a few at a time, into an increased temperature, and about a month apart. They will be found to bloom well, and succeed each other admirably, all through the winter and spring, before those out of doors can even fairly start into leaf; the only care required being to syringe them against the green fly, and if that does not keep them under, fumigate them,—and to see that they never suffer from want of water. These, however, as also summer roses, will force better the second year than the first, by shifting them into pots a size larger, trimming the plants into a proper shape, taking away the weak shoots, letting them rest, and giving but little water towards the end of the summer, except to keep them from actually flagging; putting them in their frames and removing them into heat as before, a few at a time, and a month apart. Plants of the Provence, moss, white, Damask, Tuscany and other families may be brought into the forcing house at any time from November till March, according to the season when the flowers are required; and if they are brought in at different times, they should be marked with their respective dates of introduction; and they should have a soil and root-seat as nearly as possible like those which best suit them in the open ground; and while growing, they should be watered two or three times a-week with river water or with liquid manure.

Roses are propagated from seeds, cuttings, layers, suckers, buds, and grafts. Seeds are used only when new sorts are desired; and they may be sown either on a prepared bed, or in boxes filled with very light soil, and protected in winter. Cuttings are used chiefly for the evergreen sorts; and they should be taken from the young shoots of the same year, and have each from four to six joints, and be planted in a mixture of leaf-mould and very light soil, either in pots or under a hand-glass. Layers can be put down at almost any time of the year, but do best in July, when the plants are in flower. Suckers need only to be dug up, with as much root as possible, at any time during the winter. Buds and grafts are managed in the way described in the articles Budding and Grafting. The insect devastators of rose plants are many and very mischievous; and will be noticed in the article Rose-Moth.

ROSEMARY,— botanically *Rosmarinus.* A small genus of hardy, ornamental, evergreen shrubs, of the labiate order. The officinal species, *R. officinalis*, is a native of Barbary and the South of Europe, and was introduced to Britain about the middle of the 16th century. Its stem is erect, and very branching and shrubby, and about 4 feet high; its branches are densely clothed with foliage,—and the smaller ones are quadrangular and downy; its leaves are opposite, almost sessile, linear, obtuse, entire, reflexed, upwards of an inch long, about one-sixth of an inch broad, smooth, shining and dark green above, and veined, woolly, and silvery-tinted below; its flowers are axillary and terminal, and stand on short footstalks, and have a campanulate, bilabiate, villous calyx, and a ringent, downy, pale blue corolla, variegated with white and purple, and bloom from February till May; and its seeds are four in number and oblong in form, and lie in the bottom of the calyx. This plant has long been cultivated in kitchen gardens for medicinal purposes. Its tops, or leaves and flowers, have a grateful aromatic odour, and a warm, pungent, bitterish taste; and are used for strewing in sick-rooms, for affording an essential oil, for perfuming medicinal snuffs, and for making infusions or remedies for hysteria, chlorosis, and nervous headache. The essential oil possesses fully, and the tincture very considerably, the same stimulating and aromatic properties as the tops; but these preparations, as also the tops themselves, are now far less in request than in former times,—and really do not seem to deserve much attention. Three distinct varieties of the species occur in gardens,—the silver-leaved, the gold-leaved, and the broad-leaved; and the two last of these are much taller than the normal plant. Rosemary thrives best on a poor gravelly soil, containing calcareous admixtures; but it succeeds well on any common soil. It may be raised on a shady border, in spring or summer, from slips or cuttings, properly watered, or from seed sown broadcast, and thinned to six inches apart; and when the young plants get properly advanced, they should be transplanted as required, and either allowed to grow in a head, or trained in a fan manner.

ROSEMARY. Three hardy, perennial-rooted herbs, belonging to three several genera of the umbelliferous order. One, *Athamanta libanotis*, is a white-flowered weed of the chalky pastures of England, about 2 feet high, and blooming in June and July; another, *Cachrys libanotis*, was introduced nearly 3 centuries ago from Sicily,

and has a height of about 3 feet, and carries yellow flowers in July and August; and another, *Laserpitium libanotis*, was introduced about 50 years ago from Germany, and has a height of about 20 inches, and carries purple flowers in June and July.

ROSEMARY (Wild). See Andromeda.

ROSE-MOTH,—scientifically *Argyrotoza Bergmanniana* or *Tortrix Rosana*. A very beautiful and very destructive moth of the Tortricidæ family. It acts a prominent part in the devastating of rose plants, but is far from being alone in that work. "There is scarcely any plant," says Mr. Westwood, "which is more liable to the attacks of insects than the rose. Not to mention the aphides which occasionally swarm to so great an extent, at certain seasons, on particular varieties, as to render the plant too weak to be able to accomplish its flowering; the saw-flies, several species of which feed upon the leaves, in the larvæ state; the mining *Tineæ*, whose larvæ render the leaves unsightly by tracing their serpentine track within the substance of the leaf; the leaf-cutter bees, *Megachile*, which cut out circular patches from the leaves to form the lining of their cells; or a species of the curious genus *Lyda*, belonging to the family Tenthredinidæ, which constructs a large portable case of pieces of the leaves, which it ingeniously cuts out, and then fastens round its body in a spiral direction, a course of proceeding quite unlike anything hitherto observed in the family to which it belongs; there are yet several small species of moths, which in the caterpillar state are still more injurious than all these, by gnawing away the tender parts of the shoots and buds whilst very young, so that, when the bud attains its full size, it is found to have half of the petals devoured; besides the ugly appearance given to the plant by the leaves being fastened together, prevented from assuming their ordinary elegant appearance, and partially devoured. Hence, it will be easily conceived that these insects are far more obnoxious to the rosarium than any of the others mentioned above; and, indeed, they are sometimes so numerous, especially in the early blowing varieties, that it is as common to hear the ordinary presence of a blight on the rose-trees attributed to the appearance produced by an attack of these insects, as upon any other tree."

The principal moths which attack rose-plants in this way are *Lozotœnia rosana*, *L. oporana*, *L. nebulana*, and *L. lœvigana;* the *Spilonota aquana* and the *Pterophorus rhododactylus* are also rose-feeders; the *Dictyopteryx Forskaoleana* destroys centifolious roses; the *Spilonota cynosbatella* either feeds on rose-buds, or forms rose-leaves into a web in preparation for its pupa state; and the *Antithesia salicella* feeds so, in its caterpillar state, on the leaves of the centifolious rose, as to be sometimes called the Provence rose-moth. But the *Argyrotoza Bergmanniana*, as we have said, is the most destructive of all. It is one of the smallest and most splendid of the Tortricidæ; and is described as follows by Mr. Stephens:—"Anterior wings yellow, clouded with fulvous, and obscurely reticulated with the same, with four slightly curved, nearly equidistant streaks of silvery dots,—the first abbreviated and near the base, the second before the middle, the next rather behind, extending obliquely to the anal angle, and the fourth on the hinder margin itself; cilia pale yellow; posterior fuscous, with dirty yellow cilia; head and thorax sulphur-yellow. Extremely abundant in hedges and gardens, by the sides of woods, &c., throughout the metropolitan district, and in most parts of England, at the end of July and beginning of August." The caterpillar is only about four lines long, and has a fleshy consistence, and a dark flesh colour, with a black shining head; and the crysalis has a pale reddish brown colour, and is of the ordinary form, without any of the angular projections which occur in the crysalides of some butterflies. The caterpillar is the depredator, and commences its attacks on the leaves as soon as they appear, and works two or more of them into a packet or pouch for affording itself retreat and subsistence, and burrows in the young flower-buds in order to feed upon the petals, and finally provides a retreat among the foliage for undergoing its transmutation into a crysalis.

"The extirpation of these insects," remarks Mr. Westwood, "is matter of difficulty. They are, it is true, very conspicuous in the winged state; and, if care were taken to employ children in catching and killing them just at the time when they make their appearance as moths, the laying of the eggs would be prevented, and the trees saved from the next year's broods. Bouché, however, recommends brushing the twigs of the rose in the winter with a stiff brush, which would have the effect of destroying the eggs; but as these are deposited in the most secure places, at the roots of the eyes and under the base of the young twigs, there is some danger and much difficulty in this method. An inspection of the trees in the early spring, before the insects have done much damage, will easily show the places of lodgement of the larvæ, which may then be readily destroyed by the hand."

ROSE OF HEAVEN. See Lychnis.

ROSE OF JERICHO. See Anastatica.

ROSE ROOT. See Rhodiola.

ROSE SNOWBALL TREE. See Guelder Rose.

ROSIL, or Rosills. Land of medium mechanical condition between light and heavy, or between sand and clay.

ROSIN. See Resin.

ROSMARINUS. See Rosemary.

ROSTEL. The organ of mechanical attachment possessed by rock-inhabiting cryptogams in lieu of a root.

ROSTRARIA. A hardy, annual grass of the fescue tribe. It constitutes a genus of itself, and

takes the specific name of the pubescent; but it is classed by some botanists as a brome-grass, and by others as a cocksfoot. It commonly has a height of about a foot, and blooms from June till August; but it does not possess much economical interest. It was introduced to Britain about 28 years ago from the Continent.

ROT. A disease of the liver and the adjacent viscera of sheep. It is one of the oldest and most destructive of sheep-maladies; and has been supposed to destroy more sheep than all other maladies put together. It is known to have made great ravages for centuries; and though now less virulent in some districts than formerly, it still destroys many hundred thousands of sheep almost every year.

The rot has long been peculiarly rampant along the borders of the Nile in both Upper and Lower Egypt. "It assumes its most serious character," we are told, "after heavy rains and extensive floods, and in wet countries covered with aquatic plants. It affects animals of different ages, and in all seasons. It appears every year in Egypt after the fall of the Nile; and it follows and keeps pace with the subsidence of the waters. In the superior parts of Upper Egypt, it commences about the end of July; nearer Cairo, in August; in the environs of the capital, in October and November; and in the Delta, during the months of December, January, and February. It is most obstinate, and continues longest, in the neighbourhood of the confluence of the waters. In Lower Egypt, it lasts about 120 or 130 days; and it disappears soonest, and is least fatal, when the rise of the Nile has not been considerable. Desolation and death accompany it wherever it passes. The Arabs say that this pest annually destroys 16,000 sheep in Egypt. Its victims usually perish on the 25th, 30th, 35th, or 40th day after the apparent attack." It commits great havoc also in America and in Continental Europe; and it is far from being unknown even in the mild and comparatively dry and equable climate of Australia. In many a year, it has destroyed a million or so of sheep and lambs in Great Britain; and in 1830–31, it destroyed probably more than two millions,—carrying off some entire flocks, and so terribly reducing others as to bring their proprietors to bankruptcy.

Rot appears to be a morbid condition of the liver, either preceded or accompanied or immediately followed by the presence of flukes, and producing enlargement, inflammation, and speckling of the liver itself, and great and diversified disturbance, change, and injury of the neighbouring viscera. It is believed by some veterinarians to arise from the presence of flukes,—by others, from some one or more of several influences in vegetation, in the soil, or in the subsoil,—and by others, from a diversity or complication of causes. Flukes do not seem to be always present in its earliest detectable stages; and though always numerous in its later stages, and probably great accelerators of its progress, they seem rather to be a consequence of the disease than a cause. See the article Fluke. "The appearances exhibited in the sheep that has died of the rot," says Clater, "are very singular. There appears to be dropsy not only in the belly, but all over the animal. Whenever the knife is used, a yellow watery fluid runs out; and the consequence of the existence of this fluid everywhere is, that the muscles, and that which should be firm honest fat, are yielding and flabby and unwholesome. When the belly and chest are opened, the heart is pale and soft and flabby, and often to such a degree that we wonder how it could have continued to discharge its duty. The lungs are more or less gorged with blood; and there are a great many hard knotty points, of various sizes (tubercles), in them and on them, some of which have probably broken, and the lungs are full of ulcers; or when this is not the case, the lungs are studded with innumerable little knotty points of a dark colour. The principal disease, however, is in the liver, which is much enlarged, often of double its natural size, broken down by the slightest touch, sometimes black from inflammation and congested blood, and at other times of an unhealthy lividness; but that which is most remarkable, which is characteristic of the disease, is, that its vessels are filled with flukes, which are swimming about in the bile in every duct, and burrowing into every part of the liver." "In the quantity of tallow," says Hogg, "there is not much decrease, not near so much as the extreme debility before death would seem to announce. That which enwraps the stomach and kidneys, as well as the fat dispersed through the system, has lost its suety qualities, and become a tough yellowish-coloured substance, altogether infusible by heat; in some more, in some less, but always a quantity of serum loose in the abdomen, in which the bowels float. Over the carcass are sundry yellowish spots, which are not unfrequent where fat should exist."

The earliest symptoms of rot are exceedingly obscure, and sometimes cannot be detected till the disease has gone far to establish itself in a flock. Every farmer, especially in the districts which are most liable to it, ought to examine the liver of every sheep he kills for the use of his family; for he may by this means discover the existence of rot upon his farm long before it can be revealed by external symptoms, and may in consequence adopt early and effective means to stop its progress. Whenever the liver of a slaughtered sheep is dappled with white spots or contains some flukes within its bile, no matter how generally sound the carcase may otherwise be or how few and small may be the flukes, the flock may be regarded as already under the incipient influence of rot, and ought with all speed to be subjected to the requisite regimen for checking the disease. The earliest outward

symptoms are a dulness, a languor, and a partial loss of appetite which are common to other diseases, and might readily be mistaken for indications of light fever. A fattishness attends these which does not perceptibly differ from goodness of condition for the shambles, and which induced the celebrated Bakewell actually to subject his sheep for a few weeks to rotting influences as a preparation for the market, and which has been astutely seized by many a farmer as a crisis for profitably disposing of his sheep, when only a few days' delay might allow them to be prostrated and rendered unmarketable and brought into peril by the rot. The first distinctive symptoms are paleness of the membranes, pale yellowishness of the skin, a slight tinging of the mouth and lips, and a yellowness of the caruncle at the corner of the eye. A few weeks after, the sheep begin to shrink, and become flaccid about the loins, and acquire a paleness of countenance; and, at this stage, the skin has a pale red colour, the wool readily separates from the pelt, and, when the hips are pressed, they emit a perceptible crackling sound. At later periods, the skin becomes dappled with yellow and black, the mucous membranes become more pale, the eyelids become almost white and afterwards yellow, the dullness and the loss of condition increase, the yellowness of the eyelids extends to other parts of the body, the wool separates still more readily from the pelt, the skin becomes loose and flabby, a dropsical secretion forms under the skin and extends over the body, and sometimes a large swelling, popularly called the watery poke, forms under the jaw, and then the sheep is said to be 'chockered.' Hogg, when recording the results of his very extensive observation of the precursors and symptoms of rot, says that, when a sheep is becoming predisposed to it, from the effects of bad pasturage and perverted appetite, "the stomach and bowels increase to an extraordinary bulk, become an unmanageable weight, too weighty for the constituent parts to carry about with ease, or with that facility necessary to its thriving, and by degrees the animal assumes a bad shape, that is, the belly and hind quarters become heavy and lumpish, the fore quarters low, narrow, and contracted." And he adds, "The seeds of the disease may have struggled with the constitution for some seasons; but when the following external symptoms are exhibited, it is a plain declaration that all the ingredients necessary to constitute the rot are condensed and formed into disease, and that death will immediately ensue. I shall mention them in the order in which they generally appear. About the latter end of February or beginning of March, the wool loses its healthy brown colour, becomes bleached and dead-like; then follows considerable prostration of strength; late in leaving the tathy spots, and early on them next morning,—probably would not leave at all if not urged away by the shepherd; fall always back in the ranks when the shepherd moves them forward; a sullen, lustreless eye, looking steadily at the shepherd; an œdematous swelling under the chin,—this last is a late symptom."

The causes of rot assigned by veterinarians and experienced shepherds are numerous; and though some of them are fanciful, and others subordinate, most are worthy of consideration, and serve to indicate, if not the agencies, at least the circumstances and conditions, in which the disease originates.—One assigned cause is the extrusion of the ovules of flukes by rotted sheep, and the swallowing of these ovules by sound sheep; and though this erroneously regards flukes as preceding and exciting the disease, rather than as following and aggravating it, yet it instructively points out the fact of the coexistence of flukes and rot upon a farm, and suggests the imminent danger to which a whole flock are exposed whenever any flukes can be detected in any single sheep's carcase.—Another assigned cause is miasma, proceeding from the soil and entering the lungs; and though this is proved to be fanciful by the total absence in rot of the symptoms of intermittent fever, or low fever, or inflammatory action which accompany all truly miasmatic disorders, yet it usefully directs attention to marshy grounds, or grounds of a similar kind to marshy ones, as the sites of the true causes of the disease.—A third assigned cause is a certain noxious production of a particular kind of bog lands. "I do not think," says Mr. E. May of Berkshire, "that sheep become rotted from every kind of wet land, whether drained or not, but from a particular character of the soil and subsoil, such as is inclined to bog or quagmire, although it may not have that appearance on the surface of the land, but may lie 8 or 12 feet deep. Between this subterraneous bog and the surface there is generally a hard stratum of blue clay or sand, tainted with the bog-water lying underneath at that depth; and this infectious water is brought up from the bog to the surface of the earth by means of small pipes, which are always found to form the communication between them, and called by experienced land-drainers bog-pipes. In consequence of this infectious water thus arising to the surface, a plant is produced, not of the grass-tribe, but called by some old experienced shepherds 'the sheep-rot weed;' and if sheep are allowed to feed on this land, particularly if in a hungry state, although the weed does not grow more than an inch or two above the surface, and is of a nauseous taste, they will in this state of hunger indiscriminately eat it up along with the grass, and it will, I believe, more or less infect them with rot." This, however, as well as a number of similar alleged causes, is contradicted by the existence and ravages of rot in situations where no such alleged rot-exciting vegetation exists; yet it significantly points to deep, wet, boggy subsoils as a retreat of the true cause or causes

of the disease, and suggests the necessity of all sheep-pastures being moderately dry and duly aerated, not only within the range of ordinary artificial draining, but down to as great a depth of understrata as is likely to affect the exhalations and chemical actions of the surface.—A fourth assigned cause is superabundance of water taken into the system along with the food, or excess of liquid in the herbage of pastures, or a deficiency of firm, solid, and grateful properties in comparatively succulent herbage, surcharging the body with aqueous fluid, excessively diluting the blood, and provoking an over-secretion of serous juices. But though an excessive proportion of water in food may, in several respects, be injurious to the health of sheep, it does not seem of itself to be capable of producing rot; for sheep who, for a time, live entirely on turnips, take in no less than nine parts of water for every one part they receive of solid matter, and yet do not in consequence become rotted. Still the opinion that rot arises from succulency of herbage is entertained by many eminent veterinarians and very experienced shepherds; and, in spite of being essentially incorrect, it affords broad and valuable hints respecting the measures by which the true causes may be repressed. —Some other alleged causes are, too long indulgence on flat grassy pasture which has been recently flooded,—the breathing of exhalations from pastures which, though naturally dry, have been saturated with rains and then exposed to the play of ardent sunshine,—and driving rapidly or exhaustingly or through shady lanes or along diversified tracts from an upland to a lowland pasture; and all these, as well as some others, like the four at which we have distinctly glanced, either afford some indications of the true causes, or show the circumstances in which they operate, and suggest some means by which they may be counteracted.

The true causes are confessedly obscure; and probably will not be ascertained beyond debate for a long time to come. But one of the most undoubted of them—one, too, which goes far to explain the apparent force of most of the assigned causes we have named, and which gives both meaning and amplification to all the hints suggested by these respecting the best methods of prevention and cure—is a dead and fermenting state of herbage, or of portions of herbage, on any spot or expanse of sheep-walk, which suffers a high action from subterraneous exhalations, from concentrated manurial matter, from hottish stagnant water, or from the fierce or killing combination of moisture in the soil and heat in the atmosphere. No one author whom we are aware of points to this cause in the exact light or latitude in which we represent it; yet several of the most eminent assign to some one or more phases of it either main prominence or exclusive place. Spooner says: "It appears to me, that, in addition to the consumption of food in which water greatly abounds, it is essential that this food should be in a state of decomposition (partially rotten), in order to produce the rot. And this view of the case corresponds with the fact, that heat as well as moisture is necessary to cause rot, that it is not produced while the land is entirely under water, nor until the rays of the sun have acted on the grass previously saturated with moisture." Youatt says:—"The rot in sheep, is probably the produce of ground which has been lately wet, and then the surface exposed to the action of the air. The grass and other plants, previously weakened or destroyed by the moisture, become decomposed or rotten; and in that decomposition certain gases or miasmata may be developed that cannot long be breathed, or scarcely breathed at all, by the sheep without producing rot." Hogg says:—"Feeding on land which has been formerly or is at the time pastured by cattle, is an exciting cause of rot; and the rank grass of a deep green colour, springing from the spots on which they drop their dung, is likewise vastly deleterious; as is also that kind which rises round the borders of their foot marks, after being soaked with stagnant water. This last cause affects, not individuals, but whole parcels; and in general, any misfortune or slight disease which has for a while interrupted the animals thriving on all soft tathy pastures is almost sure of introducing the rot." And Clater says:—"Rot prevails, or rather is found only in boggy poachy ground. On upland pasture, with a light sandy soil, it is never seen; and in good sound pasture in a lower situation, it is only seen when, from an unusually wet season that pasture has become boggy and poachy. It is also proved to demonstration, that land that has been notoriously rotting ground, has been rendered perfectly sound and healthy by being well under drained, that is, by being made dry. There are hundreds of thousands of acres, on which a sheep, forty years ago, could not pasture for a day without becoming rotten, that are now as healthy as any in the kingdom. We can also tell the kind of wet ground, which will give the rot. Wherever the water will soon run off, there is no danger; but where it lies upon the surface of the ground, and slowly evaporates, the rot is certain. One part of a common shall be enclosed; or if it has not been drained, at least the hollows in which the water used to stand are filled up, and the surface is levelled; no rot is caught there. On the other side of the hedge there are these marshy places, these little stagnant ponds, where evaporation is always going forward, and the ground is never dry—a sheep cannot put his foot there without being rotted. These are plain palpable facts, and they are sufficient for the farmer's purpose, without his puzzling his brains about the manner in which wet ground produces diseased liver."

The prevention of the rot is of prodigiously more consequence than the cure, and must be

achieved by every method which will render the soil dry and the herbage sound. Whatever tends to improve the value of pasturage, and the general health of sheep, tends also to prevent the rot. Thorough-draining, the extirpation of weeds, the increase of the choicest grasses, the reclamation of all waste corners and boggy spots, the promotion of uniform cleanness and sweetness throughout all the area of a farm, the careful exclusion of sheep from every field and lane where they might be likely to encounter dead herbage or putrid puddles, and the keeping of cattle stock to eat all the aftermath of low and dangerous pastures, and to consume all esculent herbage anywhere which might be somewhat hazardous for sheep, are eminent preventives, and may be regarded as essential to success. Draining alone, without due regard to the drying of the deep subsoil and of every nook and square-yard of the ground, may not, in even the most favourable situations, be sufficient. A very little more than the average amount of rain upon heavy and tenacious land, no matter how regularly underlaid with ordinary drains, or only a few minutes' trampling upon some undrained or neglected nook of a field, all whose other area is perfectly dry and sound, may defeat very elaborate precautions, and give rise to very disastrous rot. "It is surprising," remarks Clater, "how soon the animal is infected. The merely going once to drink from a notedly dangerous pond has been sufficient,—the passing over one suspicious common in the way to or from the fair, and the lingering only for a few minutes in a deep and poachy lane. Then it can easily be conceived what mischief one or two of these neglected corners, in which there may be little swamps perhaps only a yard or two across, may do in a farm in other respects well-managed, and perfectly free from infection."

One of the best known means both of prevention after contact with infected ground and of cure in the early stages of the actual disease, is the use of common salt. This substance, besides promoting the general health of domesticated animals, and aiding the salubrious qualities of their sound food, both counteracts the putrefactive tendency of dead and fermenting herbage, and kills the eggs and the young of all such small animals as flukes. See the article Salt (Common). The natural presence of salt disarms wet pastures of all the power which they would otherwise possess to create the rot; and the artificial administration of it, regularly and judiciously along with food, protects sheep from danger in many an occasional situation or during many a critical season in which they might otherwise be overwhelmed with infection. "Salt-marshes, or low lands by the sea-side or on river-sides near the sea, which districts are alternately washed by high-tide sea-water and flooded with foul inland water charged with flukes' eggs, are proverbial sound sheep-walks. Situations which, further inland, would be regarded as the worst or most sure kind of rotting land, become, from being washed occasionally with sea-water, not only perfectly sound sheep-land, but are sometimes said to benefit animals already diseased. The salubrity of such situations is presumed to depend upon the action of sea-salt, of which a small deposit will be left upon the grass, as, after the subsidence of the last tide, the aqueous part of sea-water is evaporated by the wind and sun. Any small impregnation of iodine in the sea-water is not looked upon as operating in the case. It would seem, therefore, desirable to keep a moderate supply of common salt in the stomach of sheep, whilst and for a few days after they are using unsound or suspicious pasture. The practical herdsman would probably do well, when his flock may have accidentally or unavoidably grazed upon rotting land, to give his sheep an hour's run, twice or thrice a-day, upon acknowledged sound pasture of the most commingled herbage, that the animals may pick up some plant which stimulates their digestive organs. If he would improve upon this, he might give, with some prospect of advantage too, as often as twice or thrice a-day, a little barley meal, with chaff and salt, or good hay whetted with strong brine as food, or hay tea with salt for drink."

A cure is seldom effected when the disease has advanced far, but may be very hopefully attempted when the disease is only in an early stage, and especially when it is detected through the internal appearance of a killed sheep, and has not yet shown itself in any very perceptible external symptom. The infected flock should be removed either to a good salt marsh or to an artificially salted dry pasture. A piece of pasture, of sufficient extent to allow one acre to every ten sheep, may be hurdled off, and sprinkled equally with salt at the rate of one bushel for every sheep; and the flock may be turned into it about three weeks after the sprinkling, and may continue in it till they eat the grass quite close; and another piece of the same size, and similarly prepared, ought then to be ready for their reception. As much salt as they are disposed to take may be given also with their hay or their other food. An aperient of two ounces of Epsom salt in warm gruel or water must be given to each sheep at the commencement of the treatment, and should afterwards, at some distance of time, be once or twice repeated. Food of as nutritious a kind as convenient, such as a pint of beans daily, and a large allowance of good hay, and a quantity of good gruel, ought to be constantly allowed. Many kinds and combinations of medicine, comprising mercurials, balsams, essential oils, anodynes, tonics, aromatics, and miscellaneous drugs, have been recommended; but, for the most part, are either useless or positively objectionable. Calomel, at the rate of 4 grains or so a-day to each sheep, is confidently prescribed by some veterinarians, but pronounced

valueless or worse by others. A daily dose of half a drachm of sulphate of iron and the same quantity of powdered ginger in gruel, is one of the simplest and least objectionable of the prescribed aromatic tonics. A table-spoonful of oil of turpentine, mixed with two of water, and twice administered after an interval of 3 days, is said, in the Agricultural Report of Staffordshire, to have cured 5 out of 6 rotted sheep. And the following recipe is given by Mr. Clater, and is said by Henry Cleeve, Esq., to have been used with very salutary effects,—6 ounces of powdered saltpetre, 4 ounces of fresh powdered ginger, 2 ounces of finely powdered red oxide of iron, 3½ lbs. of common salt, and 3 gallons of boiling water,—the water to be poured on the other ingredients, the mixture stirred, 14 ounces of oil of turpentine to be added when the mixture becomes lukewarm, the whole to be now put into bottles, and three doses, of 4 table-spoonfuls each, to be given at intervals of four days to each sheep fasting.

Rotted sheep, however, no matter how slightly infected or how promptly cured, always retain a taint of the disease, and are peculiarly liable to be reinfected with it, and never attain restoration to complete vigour and perfect health, and, in many instances, fall victims, some 6 or 12 months after, to an attack of hoove or of intestinal inflammation. Lambs have occasionally been produced by cured ewes,—but they are feeble in constitution, and sickly in habit; and any sheep who have had rot, no matter how seemingly well recovered or how eventually high in condition, are readily known by a butcher, from the appearance of their liver, to have been diseased. Sheep-owners, therefore, will generally find it for their interest, not only to cure and fatten up infected sheep with all possible promptitude, but to sell them as soon as they are fattened.—*Spooner on the Diseases of Sheep.—Clater's Cattle Doctor.—Youatt on Sheep.—Mackenzie on Sheep.—Hogg's Shepherd's-Guide.—Prize Essay by H. Cleeve, Esq., in the Journal of the R. Agricultural Society of England.—Papers by Mr. Hogg and Mr. King in the Quarterly Journal of Agriculture.—The Veterinarian.*

ROT (Foot). See Footrot.

ROT (Scouring). See Dysentery.

ROTATION OF CROPS. The order in which different crops are made to succeed one another in the cultivation of any one field or plot. No kind of crop can be grown from year to year on the same ground without decreasing in productiveness; and every kind of crop is benefited by alternating with some other crop, and especially by constituting only one of a series of three or four or more. Different kinds are variously helpful to one another according to their classes, their habits, their secretions, their mode of cultivation, and the order of their succession; and both individuals and series of them have a great variety of adaptations to different soils and situations. A knowledge of rotations, therefore, is most important in the science of agriculture, and absolutely essential to its profitable practice. Though a farmer should know exactly what crops are best suited to his farm, and should understand how to manage each individual of them most successfully, yet unless he knew the proper order of succession in which to grow them, he might seriously injure them all, and could not possibly cultivate them to advantage.

A knowledge of rotations is one of the main differences between the barbarous husbandry of former periods and the improved husbandry of the present day. All the agricultural writers of Britain and of Continental Europe, down to the latter part of last century, spoke of the most deteriorating courses of cropping in the same terms in which they spake of the most ameliorating, and betrayed profound ignorance of the power of certain alternations and certain successions to improve the land and augment the aggregate produce; and hence, in spite of many valuable advances in the arts of tillage, in the construction of farm-implements, and in some of the great general principles of agricultural science, they were utterly unable to indicate to their readers any such broad and short path to an overflowing granary as lies open to all moderately skilful farmers of the present day. Arthur Young was one of the earliest agriculturists who tolerably understood this great subject; and he pushed and propagated it with all his characteristic enthusiasm, and put it on the foreground of a large proportion of his writings, and owed to the successful practice and inculcation of it a main part of his proud and well-earned fame. Many able writers followed him; thousands of the best farmers of England put his instructions to the test; the whole body of enlightened cultivators throughout all the good districts of Britain speedily heard of the doctrine of rotation and assented to its importance; and British agriculture, in consequence, suddenly acquired a greater accession to its prosperity than had ever before, even at the epoch of the drill husbandry, graced and enriched its history. "No one," remarks Philip Pusey, Esq., "would now think of growing, as formerly, wheat, barley, and oats in succession; and though Mr. Hitchins, land-surveyor of Brighton, states that, in his recollection, the tenants of a gentleman living in Sussex, when a clause was introduced into their leases prohibiting them from growing more than two white crops in succession, complained that they could not hope to defray their rents if fettered by such restrictions, few good farmers at present, on light soils at least, come even up to those limits, by raising even two white crops, as they are called, in immediate succession. It is on these light lands, indeed, that a due rotation of crops has so signally succeeded, that, whereas, they were formerly considered of very inferior value, they are now more readily occupied than those heavier

soils, which, being in their nature more suited to the growth of wheat, were once valued more highly. And it is as much by the slow and almost insensible amelioration of such land, as by any increased breadth of cultivation, that the country has become in any degree capable of supporting the vast numbers which have been added to her population. A small parish might be pointed out in which an aged farmer remembers the time when a single rick was all that it could produce of wheat in one year, whereas, without any increase of its ploughed ground, that same parish now yields five or six yearly. Its sandy soil was then drifted like snow before the wind, and the scanty barley might be sometimes seen borne away also; whereas, the very fields, still called 'the Sands,' are now, by that glutinous quality which high condition imparts—by the droppings and the tread of the sheep which are fed on the turnips that now grow in garden-like order where before was a naked fallow—compacted into a brown and adhesive, though still lightish loam."

Six general laws of vegetation, or six sorts of phenomena everywhere observable in the economy of plants, may be named and briefly illustrated as involving all the principles which originate and control an enlightened system of rotation of crops,—first, that all plants more or less exhaust the soil, and naturally possess appliances for shifting their ground upon their native habitats,—second, that all plants do not exhaust the soil in the same degree,—third, that plants of different families and different habits do not exhaust the soil in the same manner,—fourth, that all plants do not return to the soil either the same quantity or the same kind of manure,—fifth, that plants differ widely from one another in the encouragement they give to the growth of weeds which either smother useful vegetation or rob the soil of nourishment,—and sixth, that all cultivated plants, particularly such as are grown in large quantities in the fields, may be classified into exhausting and ameliorating, or into groups which are cultivable mainly on their own account, and groups which are cultivable partly or mainly for the sake of affording benefit to their successors, according to the predominant principles which they abstract from the soil, or according to the balance between the effects of their obstructing action and the effects of their excreting and manuring action. We shall devote a paragraph to the succinct discussion of each of these laws; and shall afterwards speak of the causes of the exhaustion of soil by plants, the practical principles which ought to regulate rotations, and the chief or most noticeable of the many kinds of rotation which are in use, in different districts and countries, on different kinds of land.

All plants, we have said, more or less exhaust the soil, and naturally possess appliances for shifting their ground upon their native habitats; so that when any of them are cultivated from year to year upon the same piece of land, they either degenerate more and more toward unproductiveness and sickliness and extinction, or they must, by means of rotations and manurings, be supplied artificially with advantages tantamount to those which they obtain by their natural migrations. All draw out of the soil some of the principles of their nourishment or some of the substances which form their organisms and secretions; and all more or less yield up some portion of these principles or substances to other spots by the expansion of their branches, by the dispersing action of winds, by the browsing of quadrupeds, by the picking of birds, and by other agencies; and just in the degree in which they do not eventually deposit any of these principles of their nutrition in the spot whence they derived them, they deprive that spot of power to produce or maintain a future race of plants of their own species, and also any other plants which feed on the same substances. All plants have naturally a power of migration proportionate, in the rapidity and extent of its action, to the speed with which they exhaust soils and the cravings they make for new sources of nourishment. Multitudes of herbs, both annual and perennial, belonging to many families, produce winged or downy seeds, and send off these on the gentlest breezes to germinate on distant grounds; and multitudes of trees and shrubs, of the most diversified constitution and opposite habits, produce their seeds within the substance of pleasant esculent fruits, and present these to birds and other animals to be carried away by them, and deposited in other places. All seeds, in fact, whatever be their particular economy, are not less storehouses of vitality, and compendiums of organic energy, than vehicles of vegetable migration. See the article SEED. But all plants, from the sturdiest and most stationary to the feeblest and most fugitive, also travel, or are locomotively reproductive, by means of some one or other organism which developes contemporaneously with either their own main growth, or their progress to maturity, or their advance toward decay. Many a tree, on finding the soil so deteriorated as to be incapable of any longer affording a due supply of nourishment to its young shoots and twigs, endeavours to escape from the spot on which it grows by sending up side-suckers which may push their individual roots beyond the sphere of the deteriorated soil. Either a tree or a shrub, so long as it is young, healthy, vigorous, and fully fed, remains steadily in its original site, entirely enjoying the riches of the subjacent soil, and making not the remotest effort to migrate otherwise than by its seed; but when it becomes old or stunted or ill-fed, whether it be an ancient plum or pear tree in the orchard, or a decaying currant or gooseberry bush in the garden, or a starved rose-bush on the flower-border, or any other kind of lig-

neous plant in any situation whatever, it strives to send up as many or as distant suckers as will correspond to the degree in which the immediate soil has become exhausted; and, in general, whatever be its species, it makes this kind of effort, at an earlier or later period of its existence and in a lesser or greater amount of strength, proportionately to its voracity for some of the rarer principles of the soil, and to the presence or absence, the abundance or the paucity, of its making migrations by means of seeding. Similar remarks might be made, with far more force, respecting the rhizomas, the bulbs, the tubers, the offsets, the runners, and the stolons of herbaceous plants; but are, in many instances, so obvious and striking, that they will spontaneously occur to any ordinarily attentive observer. Strawberries and potatoes may be quoted as familiar examples. "And these," remarks Sir Humphrey Davy, "at first produce luxuriantly in virgin mould recently turned up from pasture; but in a few years they degenerate, and require a fresh soil, and their organization is such, as to be constantly producing the migration of their layers. Thus the strawberry by its long shoots is constantly endeavouring to occupy a new soil; and the fibrous radicles of the potato produce bulbs at a considerable distance from the parent plant. Lands in a course of years," he continues, "often cease to afford good cultivated grasses; they become, as it is popularly said, tired of them. The most remarkable instance of the powers of vegetables to exhaust the soil of certain principles necessary to their growth is found in certain funguses. Mushrooms are said never to rise in two successive seasons on the same spot, and the production of the phenomena called fairy rings has been ascribed by Dr. Wollaston to the power of the peculiar fungus which forms it, to exhaust the soil of the nutriment necessary for the growth of the species. The consequence is, that the ring annually extends, for no seeds will grow where their parents grew before them, and the interior part of the circle has been exhausted by preceding crops; but where the fungus has died, nourishment is supplied for grass, which usually rises within the circle, coarse, and of a dark green colour."

All plants do not exhaust the soil in the same degree. Though all are nourished by air, water, and the juices of the soil; yet they differ widely from one another in the quantity of the last of these which they abstract. Some require to have their roots constantly immersed in water, some require a sandy and arid situation, and some thrive only in rich, loamy, high-manured soils; and no two of these and other great classes, or even of many subordinate ones, agree in the amount of their dependence on the soil for supplies of air and moisture, and especially in the proportion of saline ingredients which they withdraw from land. "The cereal plants and most of the grasses," remarks Chaptal, "throw up long stems, consisting chiefly of fibrous matter; and these are furnished at their foot with a few leaves, which, on account of the compactness of their texture, and the small surface which they present, can absorb, comparatively, but little either of air or water. These plants therefore derive their nourishment principally from the soil, and their stalks are employed either for litter or food for animals; so that while they greatly exhaust the soil, they return scarcely anything to it,—their stalks being cut and taken away from the ground for the purposes just mentioned, and their roots, which alone remain, being dried up and drained of all their juices, in the process of forming and of maturing the seed. Plants, on the contrary, abundantly furnished with large, thick, porous leaves, that are constantly green, imbibe from the atmosphere carbonic acid and oxygen, and draw from the earth such other substances as they require for their nourishment. When plants of this kind are cut in a green state, the loss of nutritive juices sustained by the soil is less sensibly felt, inasmuch as these are in part given back to it by the roots. Such plants as are usually cultivated for fodder are nearly all of this description. There is another class of plants, which, though cultivated principally for their seed, are less exhausting to the soil than the cereal plants; we refer to the numerous family of legumes, which holds an intermediate place between the two classes of which we have just spoken. The long perpendicular roots of the leguminous plants divide the soil, and their large leaves, and thick, soft, spongy stems, readily absorb both air and water. The different parts retain for a long time the juices with which they are so abundantly impregnated, and give them back to the soil, when the plants are ploughed in at a period before they become mature; and by this means alone, the soil may be put in a condition to produce a good crop of grain. Beans are particularly valuable in this respect; while vetches and pease, and more especially the latter, are less fertilizing in their effects. Generally speaking, if plants be cut in a green state, and at the time they are in flower, whatever may be their particular nature, they do not exhaust the soil; since up to this period they have drawn their nourishment almost exclusively from the earth, air, and water. Both their stalks and roots abound in juices, and the parts remaining after the former are cut, return to the soil all that has been taken from it for the support of the plants. But as soon as the seed once begins to form, the process of nutrition undergoes a change. The plant, as before, still abstracts nutritive principles from the earth and atmosphere; but in addition to this, it now resorts to the juices contained in its stalks and roots, and these likewise are made to contribute to the formation of the seed; so that, from this time, the stalks and roots are both gradually dried up and exhausted; and when at

length the seed has reached maturity, the skeleton merely of the plant remains, and this, on being given back to the soil, returns to it but a very inconsiderable portion of what it had previously taken from it." Different groups of species, too, abstract different inorganic principles from the soil; and in proportion to the general rareness of any peculiar principles which some species abstract, or to the comparative voracity with which they abstract them, these species are exhausting. Some of the rarer principles, likewise, particularly the phosphatic and the nitrogenous, are far more plentifully abstracted from the soil by the seeds of any plants, especially by those of the cereal grasses, than by any or sometimes all of the previously formed organisms; so that the exhaustion during the formation and maturing of seeds is often greater from this cause than even from the seminal exsiccation of the stems and roots,—and the aggregate amount of exhaustion caused by any particular species of plants, as compared to that caused by any other species, may, in general, be pretty closely estimated by the proportion of these principles in the seeds. This topic, however, will be resumed and followed out in a subsequent paragraph, on the sixth and last of the general laws which explain the system of rotations.

Plants of different families and different habits do not exhaust the soil in the same manner of pasturing within it, or of exploring and diminishing its magazines of nourishment. "The roots of plants of the same family," observes Chaptal, "extend themselves in a similar manner, penetrating to the same depth, growing of the same length, and exhausting all that portion of the soil which they encompass, or with which they come in contact. Such roots as run nearest the surface, and occupy the least space, are the most divided. Perpendicular roots that penetrate far into the earth, throw out but few radicles near the surface, and draw their nourishment from a considerable depth. If in transplanting a turnip or beet, the point of the taproot be cut off, so that it can no longer run down into the soil for nourishment, it will send out small fibrous roots from all parts of its surface, which extending to a certain distance, absorb the nutritive principles from such portions of the soil as they are able to reach; and in this case the form of the root will be roundish instead of being tapering and long. It would appear, then, that the roots of plants exhaust only such portions of the soil as are in contact with them; and thus long perpendicular roots may be enabled to obtain from a soil abundant nourishment, even when its upper portion has been completely exhausted by such as naturally run near the surface. The roots of plants of the same species, and of such also as are of analogous character, uniformly extend themselves in a similar direction, whenever the character of the soil prevents not their free development; so that they all occupy the same stratum of earth, and are nourished by it. Hence it is that trees rarely flourish when, in the same ground, they are made to succeed others of the same species; and especially when sufficient time has not intervened for the roots of the first to decay, so as to afford to the stratum of soil occupied by them a fresh supply of manure."

All plants do not return to the soil either the same quantity or the same kind of manure. "All more or less exhaust the soil of its nutritive juices; but, on the other hand, they all likewise restore to it, in the remains they leave behind them, something in a degree to repair this loss. The cereal and oleaginous plants are the most exhausting of all, and at the same time return the least to the soil. When plants, in being gathered, are pulled up with their roots, they do not leave anything to repay for the nourishment which they have received. It is true that other kinds of plants consume, in seeding, a large proportion of the manure which is contained in the soil; but then the roots of a part of these penetrate far into the soil, separate its parts, and render it loose and open to a great depth; while others, again, cover its surface with their numerous leaves, and these being detached from their stalks during the progress of vegetation, compensate in part for what has been taken from it. There are some plants, also, the stalks and roots of which still retain their succulence even after their fruit is matured; and which, therefore, in their decomposition, restore to the soil a portion of the juices of which they had deprived it; certain of the legumes are of this character." The residuary matter after harvesting, whether in the form of roots, stubble, radical leaves, fallen stems or shed seeds, is of still greater importance. "It is a point of interest," remarks Boussingault, "to ascertain what quantity of elementary matter is left in the soil after each kind of crop in the rotation. Precise knowledge of this description may even be important in calculating rotations; for it is obvious that the remains of the crop now on the ground must influence that which is to follow, and in the course of a rotation the sum of the residuary matters must be regarded as a supplement or addition to the manure put into the ground at its commencement. In the systems of rotation very generally followed at the present time, the influence of these residuary matters is manifest, and it is partly by their means that we can explain how a quantity of manure, frequently very moderate, should suffice for the whole of the crops in a productive rotation. All the world acknowledge that the residues of crops compensate in greater or less degree for what is carried away in the shape of harvest, and that in some cases they even add to the fertility of the soil; for in growing crops that leave a large quantity of residue, it is precisely as if a smaller quantity were taken

from a given extent of surface. But what is the amount of residue or refuse which is returned to the soil by such and such a crop? What, in a word, is the value of this residuary matter considered as manure? This is a point upon which only the most vague and indefinite ideas are generally entertained; and it was with the purpose of substituting positive facts for mere guesses that I determined on weighing and analysing the vegetable residue of the several crops that enter as elements into our more usual rotations. My experiments were made upon breadths of land which varied from 120 to 500 square yards in extent. The clover roots and stubble were taken up with the spade, and before being dried, were freed from adhering earth by washing. The beet-leaves and potato-tops were dried at once in the oven; and it was from each the general mass reduced to powder that samples were taken for ultimate analysis, before proceeding to which, they were carefully dried in vacuo at 230° F. In the following table is a summary of the results, together with the quantity and the composition of the manure expended in the rotation.

Nature of the crop.	Produce per acre in 1839.	Produce dried at 212 degrees F.	Nature of the residues buried in the soil.	Residues obtained upon one acre.	Residues dried at 230° F.	Elementary matter of the residues.

It, therefore, appears that the refuse or residue of the several crops of a rotation represent both in quantity and in nature somewhat less than one-half of the manure originally put into the ground; I say somewhat less, because it must be remembered that in the sum of these residuary matters, the beetroot leaves and potato tops must not be allowed to stand together, the one crop naturally excluding the other, or at all events the two hoed or drill crops not entering in this proportion into the same rotation. The large quantity of organic matter restored to the soil by several of the crops in the series, consequently explains how the rotation may be closed without its being found indispensable to supply any additional manure in its course." Plants also differ widely from one another in the kind and amount of excrementitious matter which they deposit in the soil; and, for the most part, each species excretes substances which are more or less injurious to the growth of other individuals of its own species or genus, and at the same time more or less beneficial to the growth of individuals of some other species. See the article Excretion of Plants. The same species, likewise, according to the manner in which a crop of it is treated or disposed of, may differ very widely from itself as to both the kind and the amount of the manurial matter which it deposits. Many a crop which naturally exercises a very exhausting action, may be so treated as to return to the soil everything which it abstracted, or even to impart to it much additional fertilizing matter, or even to prove the occasion of depositing upon it a comparatively vast amount of very enriching manure. All crops ploughed in as green manure, and all which are allowed to decay entirely where they grow, and especially all which are fed off where they stand by sheep or other live stock, are of this class. See the articles Green Manures, Fallow, and Fold. Some of the ordinary crops of the farm, too, are mightily controlled in their power of either exhausting the soil or manuring it by the stage of growth at which they are cut down, and the degree in which their reaped produce is eventually restored or not restored to the ground. "When a herbaceous plant," remarks Professor Low, "is suffered to mature its seeds, and when any part of these seeds is carried off the farm, the plant affords, when consumed by animals, a smaller return of manure to the farm than if the same plant had been cut down before it had matured its seeds, and been in that state consumed by animals. Thus it is with the turnip. This plant is with us sown before midsummer. In the first season, it forms a napiform root, and puts forth a large system of leaves. Early in the following season, it puts forth a long stem, which bears flowers, and the seeds are generally matured about midsummer. If this plant is removed in the first stage of its growth, that is, after it has put forth its large leaves and formed its bulb, and is then consumed by animals, it returns a great quantity of manure; but if it remains until the second stage of its growth, then the consumption of its stem and leaves returns scarce any manure. The juices of the root have apparently been exhausted in affording nutrition to the flower-stem, the flowers, and the seeds. It is beyond a question, that, in order to bring a plant to its entire maturity, by the perfecting of

its seeds, a larger quantity of the nutritive matter of the soil is sucked up by it than when it is brought only to its less advanced stages. When crops of plants, therefore, are suffered to arrive at maturity, they are greatly more exhausters of the soil on which they grow than when they are cut down while they are green; and if those seeds are in whole or in part carried off the farm, the crops are exhausters of the farm, as well as of the ground which had produced them. Were the ripened seeds to be wholly returned to the soil, it may be believed that they might give back to it all the nutritive matter which had been derived from it. But, in practice, seeds are employed for many purposes, and are generally carried off the farm which produces them. When this is done in whole or in part, the plants produced are in an eminent degree exhausters of the farm, as well as of the soil on which they have grown."

Plants differ widely from one another in the encouragement they give to the growth of weeds which either smother useful vegetation or rob the soil of nourishment. "The cereal plants take precedence of all others in this respect; since their tall, slender stalks, and long, narrow leaves but very partially shade the ground, and thus not only permit such weeds as are natural to the soil to spring up in their intervals, but also encourage their growth by the protection which they afford to them against the heat and winds. Herbaceous plants, on the other hand, their stalks rising only to a moderate height, and their leaves covering the entire surface of the soil, effectually prevent the growth of everything about their roots, and consequently the soil is kept clean, and free from weeds. It must, however, be remarked, that this latter effect will only be produced, where the soil is suited to the growth of the plants, and at the same time abundantly supplied with manure, so that there shall be a luxuriant and vigorous vegetation; since, in cases where these favourable circumstances do not exist, we shall observe the same plants to be in a feeble and languishing condition, so that they become gradually overshadowed by others of a more sturdy and less useful character, until at length they are entirely displaced by them. When plants are cultivated in furrows, as is the case with roots and most of the legumes, large intervals are left which become occupied by weeds; the soil however may be kept clean in this kind of culture, by frequently passing over it with the hoe, or with some other suitable implement; and it may in this way be maintained in a state sufficiently fertile to produce another crop, especially if the plants growing upon it be not suffered to mature their seed. The seeds of weeds are often mixed with those of the useful plants, and sown at the same time; nor can the farmer be too careful in avoiding this. But much more frequently these seeds are conveyed by the winds, or deposited by water, or committed to the soil along with the manure."

All cultivated plants, particularly such as are grown in large quantities in the fields, may be classified into comparative exhausters or comparative ameliorators according to the predominant principles which they abstract from the soil. "Different genera of plants," remarks Liebig, "require for their growth and perfect maturity either the same inorganic means of nourishment, although in unequal quantities and at different times, or they require different mineral ingredients. It is owing to the difference of the food necessary for the growth of plants, and which must be furnished by the soil, that different kinds of plants exert mutual injury when growing together, and that others, on the contrary, grow together with luxuriance. Very little difference is observed in the composition of the ashes of the same plants, even although they have grown on different soils. Silica and potash form invariable constituents in the straw of the Gramineæ; and, in their seeds, there are always present phosphate of potash and phosphate of magnesia. A large quantity of lime occurs in the straw of pease and in clover. We know, further, that in certain kinds of plants, the potash is replaced by soda, and the lime by magnesia. It has been shown by the experiments of Boussingault, that the five following crops grow in succession on an equal surface of the same field once manured, removed from the soil:—

	Ingredients of the soil. Lbs.
1 Year crop of potatoes (tubers without herb)	246·8
2 " " Wheat (straw and corn)	371·0
3 " " Clover	620·0
4 " " Wheat / Fallow Turnips	488·0 / 108·8
5 " " Oats (corn and straw)	215·0
By a crop of Beetroot (roots without leaves)	399·6
" " Pease (pease and straw)	618·0
" " Rye	284·6
" " Helianthus tuberosus	660·0

These numbers express the quantities of inorganic substances removed from the same soil by different plants, and carried away with the crops. They, therefore, prove that different plants take up into their organism unequal weights of these ingredients of the soil. It is shown by a further consideration of the composition of these ashes, that they differ essentially from each other with respect to their quality. One thousand parts of beet, turnips, or potatoes, yield by incineration 90 parts of ashes; the latter are easily fusible, and contain a large quantity of carbonate of potash, and of salts with alkaline bases. Of these 90 parts, 75 parts are soluble in cold water. Two thousand parts of dry fern yield also 90 parts of ashes; but of these 90 parts none, or only a trace, is soluble in water. The ashes of wheat, barley, pea and bean straw, differ in like manner in their composition. Equal quantities of their ashes contain very unequal amounts of ingredi-

ents soluble in water. There are certain ashes of plants wholly soluble in water; others are only partially soluble; while certain kinds yield only traces of soluble ingredients. When the parts of the ashes insoluble in water are treated with an acid (muriatic acid), this residue, in the case of many plants, is quite soluble in the acids (as for instance the ashes of beet, turnips, and potatoes); with other plants, only half the residue dissolves, the other half resisting the solvent action of the acid; while in the case of certain plants only a third or even less of the residue is taken up by the acid. The parts of the ashes soluble in cold water consist entirely of salts with alkaline bases (potash and soda). The ingredients soluble in acids are salts of lime and magnesia; and the residue insoluble in acids consists of silica. These ingredients being so different in their behaviour to water and to acids, afford us a means of classing the cultivated plants according to their unequal quantity of these constituents. Thus potash plants are those the ashes of which contain more than half their weight of soluble alkaline salts; and we may designate as lime plants and as silica plants, those in which lime and silica respectively predominate. The ingredients thus indicated are those which form the distinguishing characteristics of the plants which require an abundant supply of them for their growth. The potash plants include the chenopodia, arrach, wormwood, &c.; and amongst cultivated plants, the beet, mangel-wurzel, turnip, and maize. The lime plants comprehend the lichens (containing oxalate of lime), the cactus (containing crystallised tartrate of lime), clover, beans, pease, and tobacco. Silica plants include wheat, oats, rye, and barley.

		Salts of Potash and Soda.	Salts of Lime and Magnesia.	Silica.
Silica Plants.	Oat-straw with seeds	34·00	4·00	62·00
	Wheat-straw	22·00	7·20	61·05
	Barley-straw with seeds	19 00	25·70	55 03
	Rye-straw	18·65	16·52	63·89
Lime Plants.	Tobacco (Havannah)	24·34	67·44	8·30
	" (Dutch)	23·07	62·23	15·25
	" (grown in an artificial soil)	29·00	59·00	12·00
	Pea-straw	27·82	63·74	7·81
	Potato-herb	4·20	59·40	36·40
	Meadow-clover	39 20	56·00	4·90
Potash Plants.	Maize-straw	71·00	6·50	18·00
	Turnips	81·60	18·40	
	Beetroot	88·00	12·00	
	Potatoes (tubers)	85·81	14·19	
	Helianthus tuberosus	84·30	15·70	

This classification, however, is obviously only a very general one, and permits division into a great number of subordinate classes; particularly with respect to those plants in which the alkalies may be replaced by lime and magnesia. The potato plant belongs to the lime plants, as far as regards the ingredients of its leaves; but its tubers (which contain only traces of lime) belong to the class of potash plants. With reference to the silicious plants, this difference of their parts is very marked. Barley must be viewed as a lime plant, when compared with oats or with wheat, in reference to their ingredients soluble in muriatic acid; but it would be considered as a silicious plant, if viewed only in reference to its amount of silica. Beet-root contains phosphate of magnesia, and only traces of lime; while the turnip contains phosphate of lime, and only traces of magnesia. When we take into consideration the quantity of ashes, and their known composition, we are enabled to calculate with ease, not only the particular ingredients removed from a soil, but also the degree in which it is exhausted of these by certain species of plants belonging to the potash, lime, or silicious plants. This will be rendered obvious by the following examples. A soil, consisting of four Hessian acres, has removed from it by a crop of—

		Salts of potash and soda.		Salts of lime, magnesia, and peroxide of iron.		Silica.
		lbs.	lbs.	lbs.	lbs.	lbs.
Wheat	In straw	95·31	130·51	34·75	67·55	260·05
	In corn	35·20		32·80		
Pease	In straw	154·40	198·42	354·80	371·46	46·60
	In corn	44·02		16·68		
Rye	In straw	40·73	82·78	36 00	57·82	139 77
	In corn	42·05		21·82		
Beetroot, without leaves,			361·00		37 84	
Helianthus tuberosus			556·00		104 00	

The same surface is deprived by these crops of the following quantity of phosphates:—

Pease.	Wheat.	Rye.	Helianthus Tuberosus.	Turnips.
117	112·43	77·05	122	37·84

* * * In a soil rich in alkaline silicates, but containing only a limited supply of phosphates, the period of its exhaustion for these salts will be delayed if we alternate with the wheat plants which we cut before they have come to seed; or, what is the same thing, with plants that remove from the soil only a small quantity of phosphates. If we cultivate on this soil pease or beans, these plants will leave after the removal of the crop, a quantity of silica in a soluble state sufficient for a succeeding crop of wheat; but they will exhaust the soil of phosphates quite as much as wheat itself, because the seeds of both require for their maturity nearly an equal quantity of these salts. We are enabled to delay the period of exhaustion of a soil of phosphates by adopting a rotation, in which potatoes, tobacco, or clover, are made to alternate with a white crop. The seeds of the plants now named are small, and contain proportionally only minute quantities of phosphates; their roots and leaves, also, do not require much of these salts for their maturity. But it must be remembered, at the same time, that each of these have rendered the soil poorer by a certain quantity of phosphates. By the rotation adopted, we have deferred the period of exhaustion, and have obtained in the crops a greater weight of sugar, starch, &c., but we have not acquired any larger quantity of the constituents of the blood, or of the only substances

which can be considered as properly the nutritious parts of plants. * * * If a field on which a rotation of cultivated plants has been carried on for a series of years contain an ordinary proportion of alkaline silicates, clay, lime, and magnesia, it will possess an almost inexhaustible provision of alkalies, alkaline earths, and silica; with this difference, however, that they are not all in a fit state to be used by the plant at the same time. By the mechanical operations of the farm, and by chemical means (by the use of lime, &c.), we may shorten the time in which these obtain a form fitted for the vital functions of the plant; but these matters do not suffice for its complete maturity. When phosphates and sulphates are absent from the soil, the plants growing on it cannot form seeds, because all seeds, without exception, contain compounds in which phosphoric acid and sulphur are invariable constituents. Although all the other ingredients of plants be present in superabundance, the soil will become completely sterile, when the period arrives at which it can no longer furnish phosphates or sulphates to a new vegetation. We must suppose that, for the formation of the stem and herb, for the fixation of carbon, and for the production of sugar, starch, and woody fibre, a certain amount of alkalies (in the case of the potash-plants), or an equivalent of lime (in the case of the lime plants) is necessary. But we must bear in mind, at the same time, that the constituents of blood can be formed in the organism of the plant only in quantity corresponding to that of the phosphates, however abundantly ammonia or carbonic acid may be supplied. The production of the constituents of the juice containing sulphur and nitrogen is inseparably connected with the presence of these salts. Every soil upon which a weed attains maturity is fitted for culture if that weed yields, on incineration, alkaline ashes. The alkalies of these ashes arise from silicates, so that in addition to the alkalies, soluble silica must exist in the same soil. Such a soil may contain a quantity of phosphates of lime and magnesia sufficient for potatoes and turnips, without on that account being rich enough for crops of wheat. These considerations must show the great importance which ought to be attached to phosphates in the practice of agriculture. These salts are present in the soil only in small quantity, and therefore the greater attention should be paid to prevent its exhaustion.

* * * "It follows, then, from the preceding observations, that the advantage of the alternate system of husbandry consists in the fact, that the cultivated plants abstract from the soil unequal quantities of certain nutritious matters. A fertile soil must contain in sufficient quantity, and in a form adapted for assimilation, all the inorganic materials indispensable for the growth of plants. A field artificially prepared for culture, contains a certain amount of these ingredients, and also of ammoniacal salts and decaying vegetable matter. The system of rotation adopted on such a field is, that a potash-plant (turnips or potatoes) is succeeded by a silica plant, and the latter is followed by a lime-plant. All these plants require phosphates and alkalies —the potash-plant requiring the largest quantity of the latter and the smallest quantity of the former. The silica plants require, in addition to the soluble silica left by the potash plants, a considerable amount of phosphates; and the succeeding lime plants (pease or clover) are capable of exhausting the soil of this important ingredient to such an extent, that there is only sufficient left to enable a crop of oats or of rye to form their seeds. The number of crops which may be obtained from the soil depends upon the quantity of the phosphates, of the alkalies, or of lime, and the salts of magnesia existing in it. The existing provision may suffice for two successive crops of a potash or of a lime plant, or for three or for more crops of a silica plant, or it may suffice for five or seven crops of all taken together; but after this time, all the mineral substances removed from the field in the form of fruit, herbs, or straw, must again be returned to it; the equilibrium must be restored if we desire to retain the field in its original state of fertility."

The causes of the exhaustion of soil by plants, or the natural agencies which render a constant rotation of crops in farm cultivation essential to profitable management, are so obvious from the six general laws of vegetation which have been illustrated in the six preceding paragraphs, that they scarcely need to be mentioned. One is the natural dispersion, partly by the plants themselves and mainly by birds and land animals who feed upon them, of some of the saline principles which all nutrimental plants more or less freely abstract from the soil. Another is the rapid removal from the farm, in the form of seeds and of the carcases of live stock, both of the scarcest and most valuable of the saline principles which are naturally contained in the soil, and of all the essential and most characteristic principles which are artificially supplied, from time to time, in the form of manure. A third is the removal from one field to another, or sometimes the removal from all the arable area of the farm, of such portions of the principles of nutrition as are abstracted by weeds. A fourth is the difference of range and depth in the cubic space which the roots of different plants occupy during the progress of their development and growth. A fifth is the diversity of inorganic food appropriated by different groups of cultivated plants,—such that when a field has lost the materials for feeding one group, it still possesses those for feeding another, and when it has lost the materials for feeding a second, it still possesses those for feeding a third. A sixth is the very different amount and composition and value of the residuary

matter which the different cultivated crops contribute to the ground at the time of their being mown or pulled or otherwise reaped or gathered. A seventh is the singular and exceedingly varied character and action of the excrementitious matter deposited by crops,—that of any one crop being fitted to injure a succeeding crop of the same or similar kind, and yet to benefit a properly selected succeeding crop of a different kind. An eighth is the tendency of any one crop, when repeated, to encourage the ruinous prolificity of such insects as prey upon its roots and stems, and such cryptogams as send up their sporules from the soil to feed upon its organisms,—and the contrary tendency of each of the different crops of a series to starve out all the insects and cryptogams which prey upon the others. And a ninth is the mighty facilities which are afforded by alternations of widely different kinds of crops so to modify and regulate their adaptations to one another, and their individual treatment, and the methods of disposing of them, as to control or retard or counteract any or all of the exhausting processes of a rotation by concurrent or alternate ameliorating processes.

The practical rules which ought to regulate rotations are easily deducible from what we have said, and do not require any separate proof or illustration. Some of the most obvious and important of them are, that plants which have long perpendicular roots should succeed those which have spreading and superficial roots,—that crops of the same or similar species of plants should not follow in succession, but should return at as distant intervals as shall be found to comport with general convenience and profit,—that two kinds of crops which alike or similarly encourage the growth of weeds should not follow in succession,—that crops which abstract phosphates and sulphates and nitrogenous principles from the soil, and secrete them in seeds or other forms which are not returned again to the field, should alternate with crops and with methods of treating and consuming them which shall not carry away but rather augment the remainder of these salts and principles in the soil,—that, on every farm which has been long under cultivation, crops which require much of either these or other scarce and valuable principles shall be raised only on soil which has been recently enriched with them by means of artificial manurings, and shall be followed or alternated, at sufficiently short intervals, with either crops or fallowings which shall give back to the soil as much of the rare salts and principles as they have abstracted,—that the several members of a rotation should follow one another in an order of succession studiously adapted to the conditions and changes of the soil in the successive years after fallowing or special manuring,—and that the laying down of land to grass, in a system of alternating lea with tillage, should be done when the soil is both clean and fertile. The cereal grasses, wheat, barley, oats, and rye, as grown for the maturing and carrying away of their seeds, are the greatest exhausters; the pulse plants, the pea and the bean, as grown for the maturing and carrying away of their seeds, are exhausters of less severity than the cereal grasses, and afford considerable compensatory action by means of their succulent roots and of the horse-hoe method of culture; the fibre-yielding and oleaginous plants, flax and hemp, are either exceedingly slight exhausters when pulled in flower and made to contribute only their fibre, but exceedingly severe exhausters when grown to maturity and made to contribute the entire substance of their seeds; and either the turnip, the rape, and other brassicas, when raised only for their roots and leaves, and consumed upon the farm,—or the beet, the parsnip, the carrot, the potato, and other plants of similar habit, when raised only for their roots and tubers and consumed upon the farm,—or the clover, the tare, the lucern, and other forage leguminous plants, when cut green or in flower and consumed upon the farm, are more or less non-exhausters in the ordinary method of cultivating them, and can, in most instances, be rendered powerful ameliorators either by special modes of consuming them on the ground, or by sending back to the soil the putrescent rejectamenta of their eaten produce in combination with the litter of the farm-yard. Or, to make another practical classification, the cereal crops are exhausting and befouling; the horse-hoed pulse crops are exhausting and cleaning; the green forage crops are ameliorating and sometimes befouling; the green fallow crops are ameliorating and cleaning; and the sown grass crops, continued into lea, are ameliorating and capable of being made most thoroughly cleaning.

All particular rotations, however, whether for an entire farm of homogeneous character, or for coadjacent fields of diversified character, ought to be determined with due reference to soils, local circumstances, and market profits. "Lucern and sainfoin," remarks Chaptal, "are classed among the plants which should have a place in the system of a rotation of crops; nevertheless, it is to be remembered that these plants require a deep soil, and at the same time not too compact, in order that they may freely penetrate the earth with their long perpendicular roots. Hemp, flax, and the cereal plants, require good ground, and should not be admitted into a course of crops, except in such soils as are abundantly fertile and thoroughly prepared. Light, dry soils are unsuited to the same succession of plants, as would be appropriate to those of a compact nature, and which are constantly humid. Each kind of soil, therefore, demands a particular course of crops; and every agriculturist should arrange his system according to the nature and properties of the soil which he has to cultivate. Inasmuch as in each different situation, soils will present some shades of dissimilarity, more or less

distinctly marked, according to their exposure, depth, composition, &c., the farmer should vary his cultivation in conformity to these differences, and adopt for each kind of soil the course of crops to which it is best suited. The wants of his own particular locality, the greater or less facility in getting his products to market, and the relative value of different crops, should also influence him in forming his plans of cultivation. In England, and in some of the northern countries of continental Europe, barley is made frequently to recur in a course of crops, for the reason that in these countries there is a sure and constant demand for this kind of grain, to supply their numerous breweries. In Belgium, on the borders of the Rhine, and in Russia, rye is very extensively cultivated, since the immense distilleries in these countries, and the feeding of a multitude of animals upon the remains of the grain, and other refuse matter furnished by these establishments, secure to it a certain and profitable sale. The culture, again, of plants made use of for the colouring matter which they contain, as woad and madder, is more advantageous in the neighbourhood of large dyeing establishments, than in countries where there is no consumption of these articles. In France, where the abundance and the low prices of wine hold out no prospect of an extensive demand for malt liquors, and where most of the people are accustomed to live chiefly upon bread made of wheat, this particular grain is cultivated in preference wherever it can be made to grow, while only the inferior soils are appropriated to the other kinds. There is still another consideration which should be well weighed by the farmer, before he decides upon his course of crops; and that is, that although his soil may be well adapted to a particular culture, his interest may, nevertheless, be opposed to the pursuit of it. The more abundant a commodity is, the more reduced it will be in price; and those articles should always be cultivated in preference, which will command the readiest sale, and afford the most remunerating returns. When, too, any product is not expected to be consumed upon the spot, the expense of its transportation to a market must be considered, and the facility with which it may be disposed of. The landed proprietor should first make liberal provision for his domestic animals, and his household, and the labourers on his estate, before he thinks of raising any surplus products to be sent abroad. He will therefore so arrange his system of husbandry that his lands shall at all times present such a variety of crops, as will ensure subsistence to all employed in or immediately dependant upon their cultivation. The intelligent agriculturist will likewise endeavour as much as possible to diminish the labour and expense of transport, in the culture and management of such of his lands as are remote from his dwelling; and with this object, he will cultivate in preference on lands so situated, either crops of fodder and roots that may be consumed by his animals upon the spot, or such herbaceous or other plants as may be converted into manure, by being turned into the soil. He should be careful also, in the treatment of such of his lands as are of a light and open character, and at the same time so situated as to have a considerable descent, to cultivate on them such plants only as will cover the surface with their numerous leaves, and the roots of which will bind together every part of the soil, so that it shall be protected as well from being washed away by the rains, as from being dried up by the intense heat of the sun." In districts, too, which are advantageously situated for obtaining abundance of cheap manure, such as the neighbourhoods of many sea-ports and large towns, more frequent crops of the cereal grasses and of other very exhausting plants may be profitably raised than in districts where extraneous manure is either scarce or dear; and in the latter districts, on the other hand, crops of inferior market value may often be more profitably raised with such manure as can be obtained within the limits of the farm than crops of superior market value with manure either purchased from without or withheld from other fields. The frequency of any prime crop in a rotation, likewise, ought to be mainly controlled by the same considerations which determine the aggregate character of the rotation itself; for wheat, for example, may be profitably raised on every alternate year on some rarely rich soils, or every third year on very rich compact loams, and yet not oftener than in every fourth or every fifth year on moderately good loams, and never at all on inferior loams in the best districts or on good loams in remote situations. The profitable or most suitable duration of lea, also, in every system of rotation which alternates a period of grass with a course of aration, must be determined by a variety of considerations, such as the goodness and prolonged luxuriance of the pasture, the market price of live stock, the proportional profit of grazing as compared to that of tillage, and the comparative cheapness and abundance of lime, marl, police-manure, and other extraneous fertilizers. See the articles GRASS-LANDS and FALLOW.

The oldest rotation known is called the three-field system, and was practised all over Europe centuries before the principle of rotations was recognised, and seems even to have been in use among the ancient Romans; and consisted of fallow, autumn-sown wheat or rye, and spring-sown oats or barley,—every farm or tract of arable land subjected to it, even when held in commonage by many proprietors or many tenants, being divided into three parts, one of which was in fallow, one in winter corn, and one in spring corn. Some of the earliest improvements on the three-field system consisted in the introduction of green crops, particularly clover and turnips, in the room of the fallow; and one of the

most valuable and improved of these interposed clover between the spring corn and the winter corn, and raised turnips, after a plentiful manuring, in the early months of the fallow year, and in consequence produced the four-course system or Norfolk husbandry; and this is the most remarkable of all rotations in its effects on the history of English agriculture, and continues to the present day to command as high an attention as in the first ten or twenty years after it became known, and may be regarded as, in some sense, the type of the great majority of good modern English rotations, and especially as the model of the constant alternation of a white crop and a green one which pervades all a modern English farmer's notions of the proper treatment of corn-land. Another early and valuable improvement on the old three-field system consisted in laying down the land to grass in the year of the fallow, and allowing it to lie several years in lea; and this, together with various interpolations between the spring-corn and the winter-corn, amounting in some cases to an alternation of pasture with something like an English rotation, may be viewed as the basis of the best modern rotational usages of Scotland and of the most enlightened districts of Germany.

Three rotations common at the present day in Germany are mere extensions of the three-field system, and essentially retain its errors; and one of these extends through six years, and consists of 1. fallow, 2. winter corn, 3. spring corn, 4. pease and clover, 5. winter corn, and 6. spring corn,—another extends through nine years, and consists of 1. fallow, 2. winter corn, 3. spring corn, 4. clover, 5. winter corn, 6. spring corn, 7. pease, 8. winter corn, and 9. spring corn,—and another extends through twelve years, and consists of 1. fallow, 2. winter corn, 3. spring corn, 4. clover, 5. winter corn, 6. spring corn, 7. fallow, 8. winter corn, 9. spring corn, 10. pease, 11. winter corn, and 12. spring corn. One of the German systems of alternate pasture and tillage, is practised on the moderately good soils of Holstein, and consists of 1. three or more years of pasture, 2. oats on the newly broken-up grass, 3. cleaning fallow, 4. wheat, 5. beans or barley or oats, and 6. wheat, —manure being given always with either the last or the next last crop, and sometimes also with the first wheat; another, much practised in Mecklenburg, consists of 1. two years of lea, 2. well-manured potatoes or beans, 3. oats or wheat, 4. oats or barley, 5. manured pease or tares, and 6. wheat with white clover and grass seeds; another, found to be very suitable on well-managed moderately good soils, consists of 1. two years of pasture, 2. oats, 3. well-manured beans, 4. wheat, 5. manured tares, 6. barley, and 7. mown clover and grass; and another, adapted to very rich soils in the same way as the preceding to moderately good ones, consists of 1. two or three years of pasture, 2. well-manured rape, 3. wheat, 4. manured and hoed beans or potatoes, 5. barley, 6. clover, 7. wheat, and 8. oats with clover and grass seeds.

The Norfolk rotation, or four-course system of turnips, barley, clover, and wheat, though still the most characteristic of all the English rotations, has for many years been proving itself too limited in power, and is now regarded by all scientific farmers and by multitudes of mere practical ones as quite incompetent to bring fairly or tolerably out the resources of even the most favourable districts. "Though this system," remarked Mr. Pusey in 1840, "has conferred such great though silent benefits on the country, it may be doubted whether it have not accomplished all that it is capable of, and must not pass into another. Already it has begun to fail in one of its green crops, probably in the other. The red clover, it is admitted, can be no longer repeated once in four years, and the substitution of white clover, or of rye-grass, in the alternate fourth year, or the prolongation of the course to five years, by sowing rye-grass with the clover and thus leaving the ground in grass for two years successively, are but imperfect remedies. The evil, however, is likely to increase; for in Flanders, whence the red clover was originally brought over, and where the land has been long tired with its repetition, it has been destroyed in whole districts by a grey parasitical plant called orobanche, and the only cure has been the entire suspension of its cultivation in those districts for many years. It is well known also, that in Norfolk, where the turnip has been longest cultivated, that root has become subject to a disease which distorts it with unhealthy excrescences; and it may be worth inquiry whether, apart from dry seasons and the depredations of insects, the late general failure of the turnip be not in some degree owing to its too frequent repetition. Such being the ill results of a too scanty rotation, which consists in the endless repetition of four crops, the remedy must of course be sought in a greater diversity." See the articles Clover, Turnip, and Broom-Rape. The Norfolk system, too, besides being unsuited to soils which are too heavy for turnips or too poor for wheat, is ill adapted to thin clays or merely moderate loams in all comparatively cold and late districts, which are wholly or chiefly dependent for manure on their own resources; and is even regarded by some eminent agriculturists as uneconomical on the very best soils of such districts, except in a few choice places and under the most favourable circumstances. "Whatever the climate of England may be able to do in support of this system," remarks the Editor of the Q. Journal of Agriculture, it is one which that of Scotland cannot support on any farm, however good, situated at a distance from a large town,—the source of unlimited supplies of extraneous manures. Where manure to the extent of from 16 to 32 tons per imperial acre may be applied (and that is the rate of

dunging in the neighbourhood of Edinburgh and other large towns), it is quite possible to pursue it; but no farm of Scotland could practise it on its own resources. The straw off two acres will not sufficiently manure one; and that being the case, without extraneous assistance, the fallow division of a four-course shift cannot be manured as it ought to be." Yet, on the one hand, mere farm-yard manuring is not so very greatly controlled in its action by climate as this statement would seem to imply,—and may, in all unfavourable districts, be powerfully aided or supplemented by the use of special manures; and, on the other hand, difference of climate tells, not only against the pure Norfolk husbandry, but against all constant alternations of green crop and white crop, no matter how diversified the former may be, and even though rigid care be exercised to carry all the diversity of white turnip, Swedish turnip, potatoes, tares, clover, pulse and other green crops regularly over each field on the farm.

The approved rotations in use on strong good clay soils are very numerous and diversified. A simple and unintermitted alternation of wheat and beans is practised in some parts of Kent and Essex, and in a few places in Germany; and when maintained on soil thoroughly adapted to it, and with ample supplies of suitable manure, and with assiduous plying of the horse-hoe and the hand-hoe, and during no longer a period than while the land keeps properly clean and yields a full produce, it is generally the most profitable course of cropping which can possibly be followed. An excellent rotation, based on the alternation of wheat and beans, and adapted to the same kinds of soil, but much more extensively practicable, and comprising important cleaning and ameliorating interpolations, consists of 1. bare or turnip fallow, 2. wheat, 3. clover and ryegrass, 4. oats, 5. drilled beans, and 6. wheat,—and apportions one good dose of manure to the fallow-year and another preparatorily to the beans; and this rotation or a slight modification of it, with disposal of the clover and ryegrass of the third year in either hay, soiling, or pasture, as may be found most expedient, is a very favourite rotation on the heavy soils of the Lothians. Another rotation suitable for the same soils, but still more extensive, and possessing the recommendation of being manageable with a smaller number of horses than the preceding, and therefore at less expense, consists of 1. bare or turnip fallow, 2. wheat, 3. drilled beans, 4. barley, 5. clover and ryegrass, 6. oats, 7. drilled beans, and 8. wheat; and apportions one good dose of manure to the fallow year, a second to the clover stubble of the fifth year, and a third to the drilled beans of the seventh year. "On clay lands of the best quality, and in situations where manure is plentiful," says Mr. Donaldson, "a favourite rotation has been,—1. fallow, 2. wheat, 3. clover, 4. oats, 5. beans drilled and hoed, and 6. wheat. The manure may be applied on the oat stubble, or in the spring with the beans, if the nature of the land will admit. In the most favoured situations, this rotation is well adapted for alternation, and for keeping the land clean and in proper tilth. The four years' course of 1. fallow, 2. wheat, 3. clover, pease, or beans and tares, and 4. oats, is much esteemed by many eminent cultivators, and may suit on lands of good quality; but the recurrence of the same crop is too frequent on land of any quality, and it is gradually giving way to a more extended rotation. Where the land is loamy and sufficiently mellow to admit the growth of barley, rotations of six and eight years have been followed, and include a greater change of plants from that circumstance,—1. fallow, 2. wheat, 3. beans or pease, 4. barley, 5. clover, 6. wheat or oats; or, 1. fallow, 2. wheat, 3. pease, 4. barley, 5. hay, and 6. oats. Here the clover crop is too far removed from the fallowing process, which supposes the land in the best state of preparation for the reception of these small and tender seeds. A shorter course is sometimes used,—1. fallow, 2. barley, 3. clover, 4. beans or pease and tares, and 5. wheat; and also, 1. fallow, 2. barley, 3. pease, beans, and tares, and 4. wheat; or, 1. fallow, 2. wheat, 3. pease, and 4. oats. These courses may be varied alternately with clovers in the third year. The longer courses most approved are,—1. fallow, 2. barley, 3. beans, 4. wheat, 5. tares, 6. barley, dunged on stubble, 7. clover, 8. beans, and 9. wheat; and 1. fallow, 2. wheat, 3. beans, 4. barley, 5. clover, dunged, 6. oats, 7. beans, and 8. wheat. This course may be reduced to six years, by not dunging the clover ley and making oats the last crop. And also,—1. fallow, 2. barley, 3. clover, 4. beans, dunged, 5. wheat, 6. tares, and 7. wheat. The two wheat crops are too near each other, and the fifth crop might take the place of the second. Another course has been used,—1. fallow, 2. wheat, 3. beans, 4. barley, 5. clover, dunged, 6. oats, 7. beans, drilled, and 8. wheat. If the land be clean and in tilth for clovers, this rotation claims much merit, and may be improved by exchanging the fourth and the second crops for each other. The following course possesses much merit, and joins bean and pasturage farming,—a circumstance seldom met with, and which would rarely be allowed,—1. fallow, dunged, 2. wheat, 3. grass, 4. grass, 5. oats, 6. beans, drilled and hoed, and 7. barley. In many places the land is much too hard and stiff for barley, and then the course of four and five years with beans and oats may be adopted. On the inferior soils of this description, the following course may be usefully employed,—1. fallow, 2. wheat, 3. and 4. clovers, trefoils, seeds, or cinquefoil, and 5. wheat or oats, beans, pease, and tares. The seed crops may be prolonged if thought fit, and form a course of six years. Another rotation for inferior clays has been commended,—1. fallow, 2. oats, 3. 4. and 5. grass, 6. beans, drilled, and 7. wheat; and also, 1. fallow,

2. barley, wheat, or oats, 3. and 4. clovers, and 5. oats. A crop of winter tares sometimes precedes the fallowing process after being eaten on the ground, but the mode is generally imperfect, as a very effectual part of the process is usually performed by the time the first furrow is given to the land, and the state of cultivation is much inferior to the fallows that are effected from winter ploughings which have derived the benefits of the vicissitudes of atmospheric action. The custom is very frequent on turnip soils, and even in those lands the fallowing tilth is inferior, except in some few particular cases." A new rotation for heavy clay soils is recommended by Mr. J. S. Nowlson of Hertfordshire, as one which he has found, after an experience of some years, to answer well. One-fourth of the whole arable area, on this system, is disposed in wheat; and after the wheat comes an oat crop, the one-half of which is sown alternately with clover,—after that, sown with winter tares, to be eaten off green by fattening sheep,—and then, bastard fallow for wheat; and the other half is fallowed for turnips, partly to be eaten on the land and partly drawn off,—then, fallowed for spring tares or cole to be eaten off by sheep, and then ready for wheat again; so that a farm of 200 acres will show as follows,—50 acres of wheat, 50 of oats, 25 of winter tares, 25 of fallow for turnips, 25 of clover, and 25 of cole or tares.

Rotations suitable for loams and loamy clays are more diversified than those suitable for stiff clays, and especially comprise a greater number of valuable fallowing crops, and admit an ample scope and more effectual play of cleaning culture without the aid of naked fallows. An excellent one, practised on the dry fertile loams of East Lothian, in the district around Dunbar, consists of 1. turnips, manured, and generally eaten off by sheep, 2. wheat, with clover and rye-grass seeds, 3. grass, fed off by sheep or cattle, 4. oats, 5. beans, manured and drilled, and 6. wheat; and this admits of being extended to eight years by substituting barley for the wheat of the sixth year and by adding clover and rye-grass for the seventh year and oats for the eighth; and it also, in cases of peculiar subsoil or of special wants on the farm or of controlling circumstances in the district or the market, readily allows the turnips of the first year to be substituted by bare fallow, or by any one of several drilled green crops, or the oats of the fourth by pulse, or the beans of the fifth by winter forage plants. "A course of six years," says Donaldson, "is most approved on these soils,—1. green crops, 2. wheat, 3. clovers, cut for hay or soiling, or consumed by stock on the ground, 4. oats or leguminous plants, 5. winter tares or late turnips eaten on the land, and 6. wheat; or the four years' course,—1. green crops, 2. wheat, 3. clover, and 4. oats. Beans, horse and hand hoed, may be used after the oats, along with the winter tares in portions, and alternately as the rotation goes on, and the land will thus obtain a change of plants, and the green crops may be varied to suit a similar mode of cultivation. The four years' course,—1. turnips, 2. barley, 3. clover, and 4. wheat, is too short, and the same plants recur too frequently; and it has been proposed to double the course, and extend it to eight years, thus,—5. cabbages or mangel wurzel, 6. oats, 7. tares or pease, 8. barley,—and for two years more, 9. beans, and 10. wheat; and also,—1. turnips or cabbages, 2. barley, 3. clover and tares, 4. wheat, 5. potatoes and beet, 6. barley, 7. clover, and 8. oats or wheat; and also,—1. beet and potatoes, 2. oats, 3. clover, 4. wheat, 5. turnips and cabbages, 6. barley, 7. beans, pease, and tares, and 8. wheat. The rotation of eight or more years is a repetition of that of four years, with the object of changing the plants raised as green crops, and substituting a leguminous and clover crop alternately, so that each occurs only once in the course of the rotation. But this object may be attained by varying the four years' course in the fields as they occur for cropping in succession; and if the soil be not all alike suitable for similar cropping, a change in the plants will be necessary. A course of five or six years is usually preferred, and is generally found more commodious, as it affords full opportunity of cultivating the most valuable plants, and also of profitable alternation. A course of six years has been very usefully employed,—1. turnips and other esculents, 2. wheat, 3. beans, pease, tares, 4. barley, 5. clover, and 6. oats. Unless the land be very clean and in high condition, the clover crop is too far removed from the cleaning and manuring process, otherwise the different crops are well arranged. It would be desirable that one crop be eaten on the ground as an auxiliary manure to support constant cropping, as a leguminous crop is proposed in a similar course on clay fallows; and the course may stand thus,—1. green crops, 2. barley or wheat, 3. clover, 4. oats, 5. vetches, consumed on the ground, and 6. wheat; and in five years thus,—1. turnips, 2. barley, 3. seeds, 4. pease or tares, eaten on the ground, and 5. wheat or oats. These rotations apply to clay loams of the first quality. On those of an inferior description, and on the best turnip lands, rotations somewhat different are used, including grass for two years, where there are no grass lands for producing hay and pasturage for the stock. A course of six years includes the following crops,—1. turnips and other green plants, 2. barley or wheat, 3. and 4. clover, 5. beans, pease, tares, and 6. wheat or oats, alternately on the fields. A course of five years is followed by omitting the pease and beans, and sowing oats as the fifth crop; or pease and beans may be sown in the fourth year, and followed by oats. A course of eight years has been recommended,—1. turnips, 2. wheat or barley, 3. clover, 4. and 5. pasture, 6. oats, 7. tares, and 8. wheat; or it may be limited to seven years by

omitting one year of the pasture. These courses of cropping are adapted to loamy lands, and it may be safely affirmed that no better are yet known."

An interesting table of rotations for a farm of 100 acres was proposed by Mr. Blaikie to the French government many years ago, and was published in the Gardener's Magazine of 1830, and in the first volume of the Journal of the Royal Agricultural Society of England; and though tarnished with several objectionable points, it exhibits such a great number of crops, in such suitable succession, and all adapted to dry rich loam, that it cannot fail to suggest to reflecting farmers some valuable improvements. Two of the main objections to it are that lucern requires a peculiar soil and a southern climate, and that four cereal crops in seven years, especially when three of these are wheat, can nowhere be profitably attempted in Britain except on the very finest land; and one of the special recommendations is that, notwithstanding the great number and remarkable variety of its crops, each successive one, in general, is remedial and serves as an antidote to the exhausting or befouling action of its predecessor. The table is as follows:—

First Year. Acres.	Second Year. Acres.	Third Year. Acres.	Fourth Year. Acres.	Fifth Year. Acres.	Sixth Year. Acres.	Seventh Year. Acres.
30 Wheat	5 Turnips, 5 Cabbage, 2½ Field beet, 2½ Carrots, 10 Potatoes, 3 Vetches, 2 Beans	10 Oats, 5 Barley, 15 Wheat	15 Clover, 5 Turnips, 5 Cabbages, 2½ Field beet, 2½ Carrots	15 Wheat, 10 Oats, 5 Barley	10 Potatoes, 3 Vetches, 2 Beans, 15 Clover	30 Wheat
15 Clover	15 Wheat	10 Potatoes, 3 Vetches, 2 Beans, 15 Clover	30 Wheat	5 Turnips, 5 Cabbages, 2½ Field beet, 2½ Carrots, 10 Potatoes, 3 Vetches, 2 Beans	10 Oats, 5 Barley, 15 Wheat	15 Clover, 5 Turnips, 5 Cabbages, 2½ Field beet, 2½ Carrots
5 Turnips, 5 Cabbages, 2½ Field beet, 2½ Carrots	10 Oats, 5 Barley					
10 Oats, 5 Barley	15 Clover	15 Wheat	10 Potatoes, 3 Vetches, 2 Beans	15 Wheat	5 Turnips, 5 Cabbages, 2½ Field beet, 2½ Carrots	10 Oats, 5 Barley
10 Potatoes, 3 Vetches, 2 Beans	15 Wheat	5 Turnips, 5 Cabbages, 2½ Field beet, 2½ Carrots	10 Oats, 5 Barley	15 Clover	15 Wheat	10 Potatoes, 3 Vetches, 2 Beans

10 Lucern, which lasts seven years, and is then ploughed down, and succeeded by wheat.

Rotations on the poor kinds of clay soils which will not admit of the processes requisite for green fallow crops, must necessarily owe all their restorative influences to bare fallow and to grass, and are therefore much more limited and far less diversified than rotations for either good clays or any of the loams. A good one on the best kinds of such soils consists of 1. fallow, 2. wheat, 3. grass seeds, to be either mown or pastured, 4. pasture, 5. pease, beans, or tares, and 6. oats; one, on a somewhat poorer class of the soils, consists of 1. fallow, 2. wheat or oats, 3. grass seeds, to be either mown or pastured, 4. pease, beans, or tares, and 5. oats; another, on a similar class of soils as the preceding, consists of 1. fallow, 2. wheat or oats, 3. grass seeds, 4. pasture, and 5. oats, pease, beans, or tares; and one on high-lying lands which are unsuitable for pulse or tares, consists of 1. fallow, 2. oats or barley, 3. grass seeds, 4. and 5. pasture, and 6. oats. A good rotation on the better sort of poor clay soils which have just been pared and burned, consists of 1. cole, rape, or turnip, 2. wheat or oats, 3. tares or grass seeds, 4. pease or beans, 5. oats, 6. fallow, 7. wheat, with grass seeds, and 8. a number of years of pasture; and a good one for the inferior sort of poor clay soils which have just been pared and burned, consists of 1. cole or rape, 2. oats, 3. pease, beans, or tares, 4. oats or wheat, with grass seeds, and 5. a number of years of pasture,—or, in some instances, cole and oats may be repeated in respectively the fifth and the sixth years, and the pastures commence in the seventh.

Rotations on light, poor soils of sand, chalk, gravel, and inferior loam, must be greatly controlled by the specific character of the land, by the nature of the situation, and by the local demands of the farm; and, in many instances, cannot profitably comprise either the cereal grasses or the large root crops, and need to be restricted to herbaceous and leguminous forage crops and to pasture grasses for the feeding of sheep. A good one on very poor loams consists of 1. turnips, 2. barley, with clover and grass seeds, 3. mown clover, 4. pasture, and 5. oats,—or 5. pasture, and 6. oats, pease, or tares; one for dry sandy soils consists of 1. turnips manured and eaten off, 2. barley or oats, with grass seeds, 3. 4. and 5. pasture for sheep, and 6. rye or oats; one for the better sort of sands, gravels, or chalk, consists of 1. turnips, 2. barley, 3. winter tares, eaten off, 4. rape, eaten off, 5. spring vetches, eaten off, and 6. rye grown to seed; another for the same kind of soils as the preceding consists of 1. turnips, 2. spring vetches, 3. rye, grown to seed, 4. winter tares, 5. rape, and 6. barley; one for the inferior sort of sands, gravels, or chalk, consists of 1. tur-

nips, 2. barley or oats, with clover and grass seeds, 3. clover, 4. tares, and 5. cole; one for sandy, peaty, or chalky soils which have just been pared and burned consists of 1. turnips, cole, or rape, 2. barley or oats, with grass seeds, 3. 4. and 5. grass, 6. oats, 7. tares or pease, 8. turnips, 9. barley with grass seeds, and 10. a number of years of grass; and another for the same soils as the preceding consists of 1. turnips or rape, 2. barley, with grass or clover seeds, 3. and 4. grass, 5. pease, 6. rye, 7. turnips, 8. barley, with grass seeds, and 9. a number of years of grass.—*Davy's Agricultural Chemistry.—Liebig's Chemistry of Agriculture.—Chaptal's Chemistry of Agriculture.—Goodrich Smith's Economy of Farming.—Donaldson on Manures.—Boussingault's Rural Economy.—Arthur Young's Works.—Thaërs Principes Raisonnés d'Agriculture.—The Edinburgh New Philosophical Journal.—Communications to the Board of Agriculture.—Sir John Sinclair's General Report of Scotland.—Radcliff's Report on the Agriculture of Flanders.—Buel's Farmer's Instructor.—Low's Elements of Agriculture.—Rham's Dictionary of the Farm.—Journal of the R. Journal of Agriculture.—Tower's Gardener's Manual.—Lindley's First Principles of Horticulture.—Stephens' Book of the Farm.—Dickson's Husbandry.—Dr. Dickson's Practical Agriculture.*

ROT IN TIMBER. See Dry-Rot.

ROTTBOELLIA. A genus of curious, tropical grasses, of the ophiurus tribe. Two perennial species, the perforated and the exalted, respectively 3 and 8 feet high, have been introduced to British collections from India; but they require stove heat, and are mere curiosities.

ROUGH CHERVIL. See Anthriscus.

ROUGHINGS. Aftergrass. The word is provincial.

ROUP. The most common and most fatal of the diseases of poultry. It considerably resembles glanders in the horse; and has a contagious or infectious character; and particularly attacks ill-fed fowls, in close and filthy places. The symptoms of it are swelling around the eyes, discharge from the nostrils, and a limpid but eventually purulent and fetid drivelling from the mouth. All fowls attacked with it ought to be promptly and perfectly separated from the rest of the flock; and all yards or courts or other places where it breaks out ought to be thoroughly cleaned, and henceforth kept in a tidy, sweet, and well-ventilated condition. Medicine can do little for it; yet many nostrums are prescribed by country people, and more or less possess the reputation of efficiency; and probably among the best of these is a sufficient quantity of strong solution of common salt to act as an emetic, and a mass of garlic, rue, and butter, well beaten together and crammed down the throat. The grand remedies, however, are prevention, by cleanliness, ventilation, and proper feeding, for the sound,—and warmth and thorough shelter, combined with proper ventilation, for the sick. See the article Poultry. Roup attacks not only the common gallinaceous fowls, but all the feathered inmates of the yard, even ducks and geese; and in the case of the last of these, it takes the name of gargle.

ROWAN-TREE. See Ash (Mountain).

ROWEL. An artificial means of prolonged subcutaneous irritation in the chest, belly, thighs, or other members of the horse. It commonly consists of a circular piece of leather, having a hole in the centre, and either wrapped round with simple tow, or smeared in addition with turpentine or digestive ointment; and it is inserted into an incision of about an inch in length made through the skin with a pair of strong short-bladed scissors, and widened by manual separation, to the extent of about an inch all round, of the integument from its subjacent attachments. It acts on the same principle as a blister, but so prolongedly as to produce an artificial abscess; it is of great service in many kinds of deep-seated inflammation; and as soon as it establishes a discharge, a daily dressing should be given.

ROWEN. See Aftergrass.

ROWTY. Over-rank, or too luxuriant. But the word is provincial.

ROYAL AGRICULTURAL SOCIETY OF ENGLAND, ROYAL AGRICULTURAL IMPROVEMENT SOCIETY, and ROYAL DUBLIN SOCIETY. See Agricultural Societies.

ROYENA. A genus of ornamental, white-flowered, evergreen, Cape-of-Good-Hope shrubs, of the ebony family. About a dozen species, varying in height from 4 to 8 feet, have been introduced to the greenhouses and conservatories of Britain. Most love a soil of peaty loam; and all are propagated from cuttings.

RUBBERS. The scab in sheep. See the article Scab.

RUBBING-POST. A timber post or stone pillar, set up in a field for cattle, hogs, and other domestic animals to rub themselves against. It both is useful in itself, and serves as a decoy-protection of trees, gates, and fences.

RUBBLE STONES. Loose stones or loose brick-bats, or any similar loose materials, piled on one another, for any purpose of drainage, embankment, or coarse masonry.

RUBIA. See Madder.

RUBUS. See Bramble.

RUDBECKIA. A genus of hardy, herbaceous, yellow-flowered, North-American plants, of the sunflower division of the composite order. A number of species which formerly belonged to it are now assigned to the genus *Centrocarpha* and *Echinacea*. Five or six perennial-rooted species, and one annual species, which occur in British collections, still belong to it; and they vary in height from 3 to 8 feet, and all thrive on any common soil, and for the most part bloom in autumn. Four of them, the clasping-leaved, the

digitate-leaved, the pinnate-leaved, and the cut-leaved, are readily distinguishable from one another by the form of their leaves; and the last of these has an average height of 6 or 7 feet, and blooms from July till September, and has been recommended as worthy of trial in the field as a forage plant.

RUDDLE. An ochreous or ferruginous, reddish, loose, pulverulent mineral substance, found in Derbyshire and in other parts of England, and much used, from a remote period, for marking sheep.

RUE,—botanically *Ruta*. A genus of thalamiflorous plants, principally evergreen undershrubs, constituting the type of the natural order Rutaceæ. This order is large and interesting; and occupies an intermediate station, both botanically and economically, between the wood-sorrel family and the quassia family; but it has not any uniform or very distinctive character, and might, without impropriety, be regarded as a collection of several small and successively allied groups. Some of its species are fetid herbs of the temperate parts of the northern hemisphere; some are handsome, aromatic, heath-like shrubs of the southern hemisphere, particularly of southern Africa; some are trees of the tropics, with a panicled inflorescence of pale and very small flowers; some are shrubs of Australia, with long or broad leaves and with a stellate pubescence; and some have characters or stations somewhat different from all these. Some of the genera, such as *Ailantus* and *Corræa*, contain highly ornamental plants; and still more, such as *Cusparia*, *Brucea*, *Ruta*, *Peganum*, and *Zanthoxylum*, contain medicinal species. Nine or ten hardy species, about 150 greenhouse species, and about 20 hothouse species, occur at present in Britain, and are distributed among nearly 40 genera. See the article Diosma.

The rue genus comprises about 20 species, chiefly natives of countries around the Mediterranean; but it concentrates all its main interest in the common or heavy-scented species, *Ruta graveolens*. This plant was introduced to Britain nearly 3 centuries ago from the South of Europe; and is cultivated in gardens for various small purposes of medicine and economy. It is a hardy evergreen shrub, of commonly about 3 feet in height. Its stems are branching and bushy; its lower parts are ligneous, and have a grey, rough, striated bark; its upper branches are smooth and pale green; its leaves are bipinnate, and have the pinnæ distantly set from one another; its leaflets are sessile, obovate, slightly crenate, thickish, and glaucous; and its flowers grow in terminal branched corymbs, and have a five-petalled pale greenish yellow corolla, and bloom from June till September. The leaves have a hot, bitter, nauseous taste, and a heavy disagreeable odour; they yield, by distillation, a volatile oil, which possesses all their virtues, and is the seat of all their medicinal value; and, when fresh, they are so acrimonious as to irritate and even blister the skin. The oil, the extract, and the powdered leaves are used in human medicine; and possess stimulant and anti-spasmodic properties; and are serviceable principally in hysteria, in flatulent colic, and in female complaints.—Rue loves a poor rubbishy soil, containing calcareous intermixtures; and may be grown on an unsheltered spot; and is usually propagated from slips and cuttings, planted in spring, but may be propagated also from seed. Plants of it in the garden should be kept moderate in size by cutting, and not allowed to go to seed.

RUE (Meadow). See Meadow Rue.

RUELLIA. A genus of ornamental, exotic plants, of the acanthaceous order. About 30 species have been introduced to the gardens of Britain, principally from the tropics; and upwards of 50 more are known. Two Indian ones, *R. ringens* and *R. strepens*, possess some native medicinal reputation. A few of the introduced species are evergreen undershrubs; the majority are evergreen shrubs; and most have a height of between 12 and 40 inches, and carry either blue or purple or red flowers in the end of summer or in the beginning of August. Most also love a soil of loam, and may be propagated from cuttings. The tuberous-rooted species, introduced about the middle of last century, may be selected as a sufficient specimen of the whole. "This," says Miller, "grows naturally in many of the islands of the West Indies. The roots of it are composed of many swelling fleshy tubers which run deep into the ground, and are like those of the day lily, but are smaller. The stalk rises about 4 or 5 inches high, and sends out 2 or 3 short side branches, garnished with leaves placed opposite. Some of these are small and shaped like a spatula, others are much larger; they have short footstalks, and are a little crenated on their edges. The flowers are produced on the side and at the end of the stalk; those on the side have 2 flowers upon each footstalk, which come out opposite at each joint; but those at the top sustain 3. The flowers have narrow tubes about an inch long, then they spread out to a sort of bell shape, and at the top are cut into 5 obtuse segments, which are large and spread open; they are of a fine blue, but of short duration, each flower seldom lasting in beauty one day. After the flower fades, the germen becomes a taper pod 1½ inch long, having two cells, which when ripe, burst with a touch, and cast out the seeds to a distance. It flowers in July; and the seeds ripen in the beginning of September."

RUFF,—scientifically *Machetes Pugnax*. A British bird of passage, of the longirostrous family of waders. It particularly frequents the fens of the east of England, and is common to the coast of France, and to the whole of the north of Europe. The male is celebrated for

furious pugnacity at the breeding season; and he has then a partial covering of red papillæ on his head, and a ruff or thick collar of feathers round his neck; and this ruff gives the popular name to the species, and is so variously coloured and arranged, and so fantastically diversified in the projecting position, as never to be quite alike in two individuals; and even the general plumage, at other seasons as well as the breeding one, exhibits so great diversity as to have led hasty naturalists into the describing of many imaginary species. The prevailing or most frequent colour of the head, ruff, and shoulders, is shining purplish black, barred with chestnut,—of the belly and the rump, white,—and of the rest of the plumage, chestnut, black, and brown; and the characters strictly permanent, or those at least by which the bird may always be identified, are yellowish feet, semi-palmated external toes, and a strictly sandpiper bill and carriage. The male has a total length of about 12½ inches; and the female has a total length of about 10½ inches, and is called a reeve.

RULINGIA. A genus of ornamental, Australian, evergreen, small, white-flowered shrubs, of the byttneria family. Four species, all about 2 or 3 feet high, and propagable from cuttings, have been introduced to British collections.

RUMBLING DRAIN. See Draining.

RUMEN, or Paunch. The first of the four stomachs of a ruminating animal. It is situated immediately under the termination of the gullet; and receives in a series of pellets, a large quantity of vegetable matters coarsely bruised by a first mastication; and serves by its heat, its mechanical action, and its somewhat scanty moisture, to prepare these matters for further change. It is externally divided into two saccular portions, and internally lined with a rough and papillously studded membrane; and it has a very extensile texture, and becomes by far the largest of the four stomachs, and is sometimes much stretched out by over-gorging, and in general assumes a capacity exactly suitable to the kind and the comparative bulkiness of the animal's food. See the article Rumination.

RUMINANTS, or Ruminantia. The family or order of animals who have four stomachs, and who ruminate or remasticate their food. It is the most distinctly defined of all the families of mammals; and is also the most useful to man. Its genera are the ox, the sheep, the goat, the antelope, the giraffe, the stag, the musk, the llama, and the camel; and the fourth of these comprises also the gazelle, the chamois, the oryx, and the gnou. All the ruminants have a callous pad instead of incisors in the upper jaw, and are cloven-footed, and have four stomachs and a very long intestinal canal, and have their mammæ between the thighs. The flesh of ruminants furnishes all the principal kinds of meat used by man; their milk, especially that of the cow, supplies all the produce of the dairy; their fat affords all the varieties of tallow; and their hides, their horns, and their other parts all possess great economical value. Some of the living animals, also, particularly camels, are very valuable beasts of burden.

RUMINATION. The remastication of food by a ruminant animal. Liquid or attenuated food passes at once into the third and fourth stomachs, and is not remasticated; but all other food, particularly such as consists of comparatively dry and solid vegetable matter, descends into the rumen, is there slowly macerated, passes by little and little into the second stomach, and is there separated by compression into a liquid and a solid portion,—the liquid to pass on to the third and the fourth stomachs, and the solid to be returned in pellets up the gullet for such remastication as shall reduce it to a pulp, and fit it to pass direct, by re-deglutition, into the third and the fourth stomachs. The remastication is effected while the animal lies at ease,—and constitutes what is popularly called 'chewing the cud,'—and takes place only upon matter which nothing short of an operose process can reduce to perfect pulpiness or liquidity; and the regorging which attends it differs widely from the belching or vomiting of a non-ruminant animal, and is as regularly conducted by a specially constituted organism as deglutition or absorption or secretion or any other ordinary act or function of the animal system.

In order to understand the process of rumination, we must advert to the manner in which the four stomachs communicate with the gullet, and with one another. The gullet is an extensile membranous tube, much more complicated in ruminating quadrupeds than in man, the muscles which surround it being strong, and consisting of two rows of fibres, crossing one another, and running spirally in opposite directions; and these muscles, by their contractions, so powerfully force the morsel of food begun to be swallowed onwards into the inlet of the stomachs, that the process of deglutition once commenced cannot be stopped, even by the will of the animal. The gullet enters just where the first, second, and third stomachs approach one another, and discharges itself almost equally into the first and the second. Connected with it is another organ which may be termed the cud-duct. This is sometimes a groove and sometimes a tube, according to its action; and runs from the termination of the gullet to the third stomach, with the first stomach on the left, and the second on the right, and discharges itself almost equally into the second and the third. It has thick prominent margins, which can be brought to meet so as to form a complete canal, and thus constitute a continuation of the gullet across the second stomach into the third. All these parts, the gullet, the cud-duct, the first, the second, and the third stomachs, not only communicate with one another, but all communicate by a common point, the point where the gullet

terminates, where the cud-duct commences, and towards which the three stomachs open or end. Now in the process of returning the macerated food for re-mastication, it is the cud-duct, together with the shut termination of the gullet approached to the shut inlet of the maniplies, which forms the pellets. To understand the mechanism by which these are moulded, let it be marked, first, that the cud-duct extends from the termination of the gullet to the inlet of the maniplies,—secondly, that when it contracts, it approaches one or other of these apertures,—thirdly, that of these two apertures, the termination of the gullet is habitually shut, and the inlet of the maniplies, naturally straight, can be so narrowed as almost to close by its own contraction,—and fourthly, that when the first two stomachs, compressed by the abdominal muscles and the midriff, contract, they push in consequence the materials which they contain both against the two apertures opposite to each other, and against the cud-duct opposite to the two stomachs. The two stomachs, in this manner, in proportion as they contract, push the materials contained in them between the margins of the cud-duct, and the cud-duct also contracting, causes the two apertures of the gullet and of the maniplies to approach, while the two apertures being closed and brought near together, seize upon a portion of the aliment, and detach it in the form of a pellet. The aperture of the gullet is closed during the act of detaching the pellet, because at that instant the midriff is contracted, and it only opens when the midriff is relaxed; and the aperture of the maniplies is closed, because at that instant the maniplies, as well as the other stomachs, is contracted. From these circumstances, it is obvious that the pellet must be detached, as it could not otherwise be seized by the two approaching apertures,—that the pellet must be round, for this is the form of the cavity formed by the parts of the organ employed in the process,—and that the pellet must be about an inch in diameter, for the cud-duct, when contracted in the act of forming the pellet, is about an inch in length. How beautiful a contrivance,—how exquisitely adapted to the structure and wants of the animal,—and how minutely and highly illustrative of the all-pervading beneficence and skill which everywhere shine out in the works of the Creator!

One important practical lesson suggested by the nature of rumination, is the proper feeding of cows, in order to produce the greatest quantity of milk. If they are fed on very dry food, such as hay, the greater portion of fluids in the blood will be spent in the process of rumination and digestion, and the milk will be scanty; but if they be fed on aliment which abounds in liquid, such as mangel wurzel or brewer's grains, and distiller's wash as in Holland, they will ruminate much less, a less quantity of saliva will be wanted for chewing the cud, and a large proportion will go to the production of milk, though this will be thinner, and not so rich in cream as the milk produced from drier food. It is questionable whether cows fed wholly on distiller's wash would ruminate at all any more than calves, which so long as they suck, never ruminate.

Another important practical lesson has reference to the giving of medicines, and is stated as follows by Clater:—"We may, to a very great extent, send medicine into what stomach we please. We may give it in a ball, and it will fall into the paunch, and thence go the round of all the stomachs: or it may be exhibited in a fluid form, and gently poured down, and the greater part of it passed at once into the third and fourth stomachs. That which is meant to have a speedy action on the constitution or the disease should be given in a fluid form. That also which is particularly disagreeable should be thus given, otherwise it will enter the paunch and be returned again in the process of rumination, and disgust the animal, and, perhaps, cause rumination to cease at once. This would always be a dangerous thing, for the food retained in the paunch would soon begin to ferment, and become a new source of irritation and disease."

A third important practical lesson has reference to the sweating of the domestic ruminants, particularly sheep. Sweat is a production of the fluid portion of the blood, or arises from the same source as the salivary secretion employed in rumination; and hence the flow of it is more to be dreaded in ruminating animals than in others, inasmuch as it greatly diminishes the supply of fluid which ought to be employed in rumination. If sheep are sweating while they ruminate, there will be two evacuations of fluid at the same time, the body will be dried, and the blood exhausted and heated by the loss, while thirst will supervene, so as to make them drink till they are incommoded and their temperament altered. Sweating is also hurtful to sheep in other respects; for the fibres of their wool are thereby deprived of a part of their nourishment, which the sweat carries out of their body, while the heat which occasions the sweat causes the wool to grow too rapidly to acquire sufficient consistence.

RUMEX. See Dock.

RUNDALE. A peculiar and most mischievous kind of land-tenure in some parts of Ireland. It distributes each natural division of a tract or townland among all the tenants or small proprietors of the whole tract; and is therefore the very worst possible kind of commonage, and may be regarded as the modern and aggravated form of the old English system of common-field, and the old Scotch system of runrig. See the articles Common and Runrig. An occupant by right of rundale may have his proportion of a tract in 30 or 40 different patches, all without fences, and some so very small as not to need more than half a stone of oats to sow them. All rundale occu-

pants regard themselves as entitled to a portion of each kind of soil or surface in a townland; and whoever has a very good piece at one extremity, may have a very bad piece at the opposite extremity, and a middle-rate piece in the centre, and two or ten or twenty pieces of intermediate quality between. This miserable system produces endless confusion, trespasses, disputes, litigation, and fighting, and effectually prevents all georgical improvement, and even incites all occupants to cultivate the land with the least possible amount of manuring and labour. On a certain day in autumn, all the cattle belonging to a townland are brought from the mountains, or outlying pastures, and sent indiscriminately over all the arable land, and kept there in perfect commonage till a certain day in spring; so that no man can grow clover or other green crops, or can allow a late crop of potatoes in a backward year to remain in the ground till they ripen, or can perform any winter-fallowing operations, or can practise any system of husbandry whatever except the rudest and most unproductive. Even if a piece of bog or mountain should be reclaimed by any man of more than ordinary industry or enterprise, it is liable to be taken from him as soon as he has got one crop off it, and divided among all the tenants of the townland.

RUNRIG. An old Scottish tenure of land, of the nature of commonage. A large portion of the arable land of Scotland was formerly under this tenure; and seems to have been originally laid out in alternate ridges belonging to different vassals, and afterwards became separate properties in perpetual feu-rights, similar to the English copyholds of inheritance. "The origin of these intermixed patches of property in arable land," says Sir John Sinclair, "has been endeavoured to be accounted for in different ways. Some have conceived that it was on purpose to establish a common interest in the defence of their lands or their productions among the occupants; but it was more probably occasioned by the poverty of our ancient peasantry, requiring two, four, or even more, to unite in furnishing the numerous oxen then requisite for working a plough." This destructive system began to be broken up under the authority of an act passed in the year 1695; and it long ago ceased to disgrace any of the improved districts of the kingdom; yet it still leaves traces, or even remains entire, in some of the remote parts of the Highlands and Islands.

RUNT. See Cattle.

RUPPIA. A small genus of floating plants, of the order Fluviales. The sea ruppia, or tassel pondweed, *R. maritima*, is a perennial indigen of the salt-water ditches of various parts of Britain. Its herbage is submersed; and its flowers have a herbaceous colour, and bloom in July.

RUPTURE, or Hernia. The protrusion of some part of the intestines from their proper cavity. In the horse, it is not frequent; and is caused by accidents, kicks, over-exertion, and violent straining; and may be distinguished from a swelling or tumour by disappearing beneath the pressure of the fingers; and reappearing as soon as the pressure is withdrawn; and in some cases is so trifling as not to cause the animal any inconvenience, but in general is sufficiently serious and peculiar as to require treatment by a veterinary surgeon. In the cow or the ox, it is sometimes very bad from goring or from some similar accident, and can be properly dealt with only by a person of much surgical skill, and certainly should never be tampered with in the way of trying to return the bowel by mere manipulation. Some calves are born with rupture; and all such should, with the utmost care and speed, be fattened for the butcher.

RUPTUREWORT,—botanically *Herniaria*. A genus of curious, green-flowered plants, of the paronychia family. Their name alludes to their supposed medicinal virtue. The smooth species, *H. glabra*, is a procumbent or trailing, perennial-rooted indigen of the sandy and gravelly soils of some parts of England. Its root is tapering and somewhat woody; its leaves are stalked and obovate; and its flowers are small, and grow in dense clusters, and bloom in July. The herbage of this plant has a saltish taste, and possesses astringent and diuretic properties; and the juice is alleged to have the power of clearing away specks from the eyes.—The hairy species, *H. hirsuta*, resembles the smooth in at once character, duration, height, and habitat; but is more rare, and has a rough stem and hairy leaves, and blooms in July and August.—Two annual species, and four or five perennial ones have been introduced from the South of Europe.

RUSCUS. See Broom (Butcher's).

RUSH,—botanically *Juncus*. A genus of endogenous, herbaceous, coarsely grassy-looking plants, constituting the type of the natural order Junceæ. This order is nearly allied, on the one hand, to the sedge family, and, on the other, to Fluviales or pondweeds and duckweeds; but it wants uniformity or close definedness of character, and comprises plants of somewhat widely dissimilar appearance. A few of its species carry pretty yellow flowers; but most are rigid, coarse, unpleasant-looking weeds. One genus has the habit of a low palm; and the others present more or less the appearance of carices, sedges, or stiff, smooth grasses. Some species, particularly some of the British ones, indicate by their presence a deep and rich, though moist and neglected soil; and other species, amounting to the great majority, occur only on lands which are waste or more or less barren. About 60 hardy species and about 20 tender and half-tender ones have a place at present in the British Hortus; and three-fourths or so of the whole belong to the two closely allied genera, juncus and luzula,—and the rest are distributed among five other genera.

A number of the true rushes, or species of the genus juncus, occur largely in the moist pasture lands of Britain; and are significant indicators of wetness of the soil, and generally wasteful occupants of ground which a proper course of draining and georgical improvement might render highly productive. They are cropped, in their young state, by cattle,—and are converted, in upland districts, into hay; but they constitute very inferior herbage in all sorts of pastures and meadows, and are downright, destructive, abominable weeds in every kind of alternately grass and arable land. The extermination of them always requires thorough subsoil draining,—and sometimes the application of saline or calcareous top-dressings, or of sand, road-scrapings, or some similar substances,—and, in the worst cases, a subsequent course of tillage; and it need never be attempted by merely breaking up the surface,—for though this may temporarily subdue them, it makes no true or vital impression on them, and will allow them to reappear in all their power and plenteousness as soon as the land is laid down again to grass.

The conglomerated rush, *J. conglomeratus*, is one of the most frequent in the low meadows and moist low pastures of all parts of Britain; and is often called the common rush. It has a height of about two feet, and blooms in June and July. This species and the next four which we shall name, are used for making rush-lights and for a number of well-known economical purposes; but have, for a good number of years past, been mainly substituted in the latter by one of the most common of the club-rushes. See the article Club-Rush.—The soft or effuse rush, *J. effusus*, abounds in the same sort of situations as the conglomerated rush; and has usually a height of about 3 feet, and blooms from May till August. This species is cultivated in some parts of Eastern Asia for making floor-mats.—The sea rush or lesser sharp sea rush, *J. maritimus*, occurs in salt marshes in various parts of Britain; and has usually a height of about 4 feet, and blooms in August.—The sharp rush or greater sharp sea rush, *J. acutus*, occurs on the sea coasts of various parts of Britain; and has usually a height of about 6 feet, and blooms in July and August.—The glaucous rush, *J. glaucus*, inhabits the same kind of situations as the conglomerated and the soft species, in some parts of England; and has a height of two feet, and blooms in July; but is comparatively scarce.—The sharp-flowered rush, or sharp-flowered jointed rush, or sprit, or sprat, *J. acutiflorus*, abounds in many sorts of moist ground in both the high and the low districts of Britain, and often forms the greater part of the herbage of bogs and peat-meadows; and though not readily eaten by any of the grazing animals, except in the absence of better food, yet, when made into hay, is somewhat freely eaten by the hardier breeds of cattle. It usually has a height of about two feet, and blooms in July and August.—The other indigenous species, together with their respective heights and habitats, are the Baltic rush, 20 inches high, on the sea coast,—the filiform rush, 6 inches high, in bogs,—the squarrose rush, 6 inches high, on sandy and gravelly heaths,—the shining-fruited rush, 2 feet high, in meadows and moist pastures,—the blunt-flowered rush, 20 inches high, in marshes and very wet meadows,—the three-flowered rush, 6 inches high, in upland bogs,—the two-flowered rush, 3 or 4 inches high, in upland bogs,—the bulbous rush, 12 inches high, in moist grounds,—the toad rush, an annual, the only indigenous species not perennial, 6 inches high, in wet shady ground,—the marsh rush, 12 inches high, in English turfy heaths,—the supine rush, 6 inches high, on Scottish mountains,—the chestnut rush, 12 inches high, in the Scottish Highlands,—the many-headed rush, 2 feet high, on Scottish mountains,—and the three-leaved rush and Gesner's rush, both but a few inches high, on some mountains of the Scottish Highlands.

Six species of the genus luzula are also indigenous,—the hairy rush, 6 inches high, and the tall or greatest rush, 2 feet high, in the woods of Britain,—the field rush, 6 inches high, in the barren pastures of Britain,—Forster's rush, 10 inches high, in the woods of England,—and the spiked rush and the arched rush, respectively 6 and 12 inches high, on the mountains of Scotland.

RUSH-NUT. See Cyperus.

RUSKY. A circular seed-basket, commonly made of rows of twisted straw, and provided with handles and a bottom-rim. It is used for carrying seed-corn to the sower, and is carried either on the head or in the arms.

RUST. Oxidized iron. It rapidly forms on the surface of any iron which is exposed to the joint action of humidity and the atmospheric air. It mainly consists at first of the protoxide of iron; but it afterwards passes gradually into the hydrated peroxide. It always contains ammonia. The means of preventing the formation must be such as either to secure perfect and constant dryness or to exclude the access or resist the action of humidity. The common method of a coat of paint acts in the latter way. See the article Iron.

RUST, Red-Rag, Red-Gum, and Red-Robin. Diseases of grasses and corn-plants, caused by minute fungi of the coniomycetous order. They are commonly ascribed by botanists to two species of the genus Uredo,—*U. rubigo* and *U. linearis;* but they probably arise from mere varieties, or from various ages and conditions, of the mildew fungus. See the article Mildew. They attack wheat at all stages of its growth; and are found sometimes on the young blade, occasionally on the stem, and very generally in the glumes and the paleæ, even after the grain is formed. The fungi have commonly a ferruginous, a yellow, a brown, or an orange colour; and those which have spherical spores are usually

said to be the *U. rubigo*, and those which have oblong ones the *U. linearis*. They form oval spots and blotches; and when the spores have burst through the epidermis, they are readily dispersed. The rust, the red-rag, and the red-robin varieties make the plants look as if they were dusted with a rustiness of some colour from yellow to brown; and the red-gum variety occurs only on the ear, and appears like gummy exudations, and consists in groups of red, minute, glutinous globules, interspersed with transparent fibres. Professor Henslow found the red-rag more common within the range of his observation than any of the other kinds; and he says, "It abounded in the form of an orange powder which exuded from the inner surfaces of the chaff-scales, but was scarcely, if ever, to be seen in the skin of the seed. It might also be traced in patches beneath the epidermis of the straw; but I did not observe that it had burst through the epidermis anywhere, excepting on the inside of the chaff. It seemed to prevail more among the rough-chaffed wheats than others." The rust, in its several varieties, is not so injurious as the true mildew; and is perhaps the least destructive of all the parasite diseases which attack wheat in Britain; and is somewhat readily dissipated by an outburst and continued play of sunny weather; but is generally more injurious, when it appears, in the later stages of growth, on the glumes and the paleæ, than when it appears, in the earlier stages, on the blade and the culm. The methods of preventing it are the same as in the case of mildew.

RUT. A small, narrow, surface drain, made intentionally with a spade, or unintentionally with the wheel of a cart or carriage.

RUTTING SEASON. The season of the lower animals, in their respective species, being in heat for pairing or for copulation.

RUTA. See Rue.

RUTA BAGA. See Turnip.

RYE,—botanically *Secale*. A genus of cereal grasses of the wheat tribe. The two glumes or outer chalf of its spikelets are bristly or awl-shaped, while those of wheat are large and so far valved or hollowed as to include a considerable portion of the lower floret; and this is the principal botanical distinction between the two genera.

The History of Rye.—Great obscurity hangs over the early history of rye; and considerable difficulty continues to the present day to attend the determination of some of its species and varieties. Certain interesting ancient notices of cereal grasses are thought by some commentators to refer to rye, and by others not; some plants which the botanists of a former age regarded as species of rye, are now assigned to the genera Triticum and Agropyrum; and two or three varieties, or perhaps species, which continue to be called rye, either hold a doubtful place between rye and wheat, or are not sufficiently known to be spoken of with certainty. Yet a few old facts respecting rye are well authenticated, and at the same time possess considerable interest.

Rye has been variously supposed to be a native of Crete, of the Crimea, and of the Levant or of Egypt; but it possesses the constitution of a plant inured to the coldest regions, and grows most abundantly beyond the Yakutsk on the surface of a frozen subsoil, and seems, on the evidence both of its own nature and of some of the earliest records of it, to have been introduced to all other countries where it is found from some northerly part of Asiatic Tartary. The grain mentioned by Moses and Isaiah, which the authorised English translation of the Sacred Scriptures calls rye, and by Herodotus, which some old scholiasts regard as rye, appears to have been the species of wheat formerly called *Zea spelta*, and now called *Triticum spelta*, and popularly spelt. Rye does not seem to have been known to Aristotle or Dioscorides, and is not mentioned by Cato, Virgil, Columella, or Varro, and may therefore be inferred to have held no place among the ancient agricultural crops of Greece or Italy. Pliny, however, describes it as cultivated by the Taurini in the part of Cisalpine Gaul which now constitutes Piedmont, and says that they call it Asia,—a circumstance which possibly may point to their ancestors having brought it with them remotely from Asiatic Tartary, and immediately from the valley of the Danube.

"Rye appears to have been in Pliny's time, as now, cultivated not alone for its grain, but also as fodder for cattle; for after saying, that rye and farrago (which he afterwards explains to be a thick sowing of tailing wheat mixed with vetches) required no other cultivation than a harrowing, indicating thereby that rye is best suited, as the fact is, to a light sandy soil, since a strong soil cannot be cultivated by a mere harrowing,—and that in Africa, barley (which Pére Harduin expounds to mean winter barley) is used for the same purpose, being sown together with a degenerate vetch, which Pliny calls cracca,—he adds, that all the articles which he has enumerated are destined for cattle food. Pliny further says, that rye is the worst of grain, and only fit to repel famine; that it is productive, but is of a slender straw; that it is miserable for its blackness, but remarkable for its weight; that wheat is sometimes mixed with it to mitigate its bitterness,—but that even so, it is most unacceptable to the stomach; that it grows in dry soil, and makes a return of a hundred grains for one, and itself suffices for manure, thereby probably meaning, that as it is a good forager, it will grow without dung. When we recollect that the means were familiar to Pliny of comparing rye with the splendid wheats of Italy, we may not, perhaps, much wonder at his low appreciation of this homely though nutritive and useful grain. Its use at that time as a bread-stuff was

probably confined to the elevated and inclement regions, where the chilling blasts descending from the Alps rendered the culture of superior grain precarious and unprofitable."

Rye was known and cultivated in Britain at a very early period. Spelman's Glossary speaks of ancient rents reserved in rye, showing it to have been anciently in extensive cultivation; and Worlidge and Ray, who wrote in the 17th century, enumerate it among the plants then commonly cultivated in Britain,—and the former assigns it a rank as a bread-stuff next to wheat. A practice long prevailed, both in Britain and in other lands, of sowing rye and wheat together; and the name given to this mixture was meslin or maslin,—a Norman word signifying corn, and seeming therefore to indicate a considerably high antiquity in this practice, and a corresponding antiquity and prevalence of the ordinary cultivation of rye. But the reputation of this grain as a bread-stuff, in Britain, gradually diminished during the progress of modern agricultural improvement, and may now be regarded as extinct. Yet rye is still extensively cultivated as a bread-corn throughout Poland, Russia, Switzerland, much of Germany, and other parts of Continental Europe; it is cultivated, both as a bread-corn and for other purposes, in some of these European countries, in some parts of America, and in other parts of the world; and it has of late years begun to challenge high attention as a forage-plant, as well as to maintain an old character for some important though comparatively small economical uses, in various districts of Britain. Its present rank among field-plants, therefore, may be regarded as one of permanent and reviving interest.

The Different Kinds of Rye.—The corn rye, *Secale cereale*, is the principal species, and comprises a number of varieties. It is an annual, and has ordinarily a height of about 3 feet, and naturally blooms in June and July.

Winter rye, *S. c. hybernum*, is the kind most generally cultivated in Britain; and is supposed to have been originally introduced from Tauria, while the normal corn rye was introduced from the Crimea. It is particularly adapted for poor moorish soils in upland situations, and, in general, for all sorts of inferior arable soils which are incapable of producing wheat. It serves, more or less, all the several purposes for which rye of any kind is wanted; and in some parts of Scotland, particularly in Orkney and in Argyleshire, it is grown exclusively for the manufacture of straw-plait. It is sown in autumn, and stands over winter, in the same manner as winter wheat; and therefore has a kind of biennial character.

Spring rye, *S. c. vernum*, grows more uprightly from the commencement than the winter rye, does not tiller so well, and is about 12 days earlier. Its culm, also, is more slender and a good deal shorter; its ear is shorter; and its grain is rather smaller, but heavy and of excellent quality. Yet notwithstanding its several and wide differences, it maintains them only when treated strictly as a spring corn; for when frequently sown under similar circumstances to those of winter rye, it becomes identical with that variety in both habit and appearance. Spring rye seems to have been known in Britain at least 70 years ago, yet has never come into extensive cultivation in this country. It was regarded by M. Vilmorin, in the intensely dry summer of 1818, as the best of the cereal grasses then known in France for growing rapidly and affording the earliest and readiest supply of green food to starving cattle in a year when all verdure was burnt up,—and it probably is surpassed in this important adaptation by no agricultural plant known at the present hour, except perhaps the *Setaria germanica* or moha or German millet; and it has, for some little time past, been getting into greatly extended cultivation, as a bread-corn, in some parts of France, and is there sown in March. A subvariety of it, grown in Germany, and called the great spring rye, is taller, and has longer ears, and is a little later, than the kind usually cultivated in France.

The Roman rye seems to be intermediate in character between the winter rye and the spring rye. "We owe this interesting variety," says the intelligent author of Le Bon Jardinier for 1846, "to the Marquis Doncieu de Chaffardon, whose son brought it, some years ago, from the environs of Rome. It is distinguished from other varieties readily by the lightness of its colour, and eminently by the great size of its grain. In autumnal sowings of it in France, it has completely borne the winter, and has remained a comparatively fuller plant than other winter rye grown by its side; and in spring sowings, it has freely matured itself to seed, and for the most part in good season." But it cannot yet be said to have acquired a steady character even in France; and as to Britain, it is but newly introduced, and has not yet been duly tested with the climate.

The midsummer rye or St. John's day rye is the most valuable of all the known and tested varieties of rye to the British farmer. It was introduced to France from Tuscany by M. Vilmorin, and from France to Britain by Dr. J. S. Duncan and W. P. Taunton, Esq.; and, for some time past, it has been rapidly rising in favour and greatly extending in cultivation. It differs very much from both the winter rye and the spring rye; it is considerably later in running to ear and in ripening than the winter rye; and it produces longer straw, much longer ears, and more root foliage. In France and other parts of the Continent, it is often sown in the end of June, and eaten down with sheep in autumn and spring till the latter part of April, and then allowed to run to seed; and it has the reputation of yielding a larger produce in grain when thus

treated than if it were grown in the usual way. The great length of time which it occupies between brairding and running to seed peculiarly qualifies it for this kind of treatment; and a habit which it has of powerfully tillering or of throwing up many stalks eminently fits it for being grown for soiling at so advanced a period in the season as the third or fourth week of June. On suitable soil, and when sown between the 21st and the 30th of June, and pressed down on light land by rolling or sheep-treading, it soon throws out a great mass of foliage, and eventually rises to the height of 6 or 7 feet, and may yield so much as 11 London loads of straw per acre when left for seed. "The mode of operation by which the St. John's day rye becomes so productive," says Mr. Taunton, "is its tendency to throw out extremely numerous branches from the same root; or, as it is expressed by farmers, to tiller out greatly; from which quality it has obtained its name of *multicaule*, or many-stalked rye. These branches are not all produced at the same time, but successively; and the season for their production is limited to the period during which the plant is not excited to throw up its culms; for after the culms have begun to rise, there is little or no addition made to their number. It is important, therefore, to the increase of the bulk of the crop, that the period between the germination of the seed and the rising of the culms should be protracted as long as possible. The longer it is, the more numerous will be the branches from a single root. This, therefore, is the cause of the marked advantage attendant upon sowing at midsummer." If the young crop be mowed or fed down once or twice before winter, it will grow vigorously again,—and a strong temptation to this treatment is held out by the luxuriant mass of herbage which it presents by about the month of October; but in all ordinary cases, it will compensate far better if left alone till spring. "The root-leaves," says the writer we have just been quoting, "neither die away in the same degree as those of the barley, nor are materially injured by the frost; and so soon as the influence of the vernal sun returns to the earth, the young leaves, under the shelter of these old leaves, shoot up among them, and attain nearly the same height as their nurses, regardless of the north-easterly winds; and the mixture of the old and young leaves furnishes not only a more bulky, but a heartier and safer meal for a sheep than the tender young shoots alone would do, for the earliest shoots of almost every sort of herbage often have too aperient a quality; while, if there had been no old leaves remaining, but if these new leaves had to rise into the cold air from the naked ground, they would not at that time venture to put out a shoot. This crop realizes, in an eminent degree, the benefits contemplated by the late Arthur Young, in strongly recommending the farmer to preserve the old fog, or aftergrass, of pasture fields, untouched through the winter, for the food of ewes and lambs in spring. You not only have the foliage you had in November, at a time when its specific value is doubled or trebled, but you have its bulk doubled also. There may, indeed, be cases, when an early sowing, combined with very rich or highly manured ground, or a soil fully stocked with charlock, may produce such a mass of autumnal foliage that it would in a long winter rot on the ground. In such a case it might be necessary to mow or feed it before winter; but that is an extreme case."

Cooper's early broad-leaved rye was brought into use about 3 or 4 years ago by Mr. Thomas Cooper of Ardleigh Wick, near Colchester, in Essex; and is an extremely valuable variety, of similar properties to the St. John's day rye, but considerably earlier. When sown in the beginning of September, it exhibits a surpassingly dense herbage and rich verdure in January and February, and becomes fit for soiling about the middle of April, and attains as great a height in the beginning of May as St. John's day rye sown at midsummer, but is liable to prove wofully deficient in grain at the time of harvest. Mr. Baker of Writtle in Essex, speaking apparently of this rye, says, "I know of no other food for early spring use, as a substitute for hay, equal to this." And Mr. Taunton says, "I strongly recommend to every farmer in the southern counties, who studies the increase of manure, and frugality in his stable and stall expenditure, to sow every year a certain breadth of Cooper's early rye, sufficient to last him from the middle of April to the second week in May or middle of that month; and a somewhat larger breadth of the St. John's day rye, to succeed the former, being sufficient to last him to the third or fourth week in June. With the aid of these two, he can well keep his stock tied up until the racer vetches, winter barley, common winter vetches, and clovers come in, and place him at his ease, with a latitude of choice of green fodder."

The many-stalked Russian rye, though sharing the name many-stalked with the St. John's day rye, bears a nearer resemblance to the common rye of the French than to that variety. Its leaf is broader and straighter and of a more tender green colour than the St. John's day rye; its time of coming to maturity is somewhat less late; and its grain is larger, more abundant, and of better quality. It does not tiller out more than the common French rye; it is longer eatable as green food for cattle than the English rye; and, though by no means equal to the St. John's day rye for fodder, it must be regarded as a very large, beautiful, and productive variety.

The Tyrolese giant rye was introduced a few years ago from the Tyrol, and has a general resemblance to the St. John's day rye; but tillers much less, and is considerably earlier, and does not afford so good a supply of green food for cattle. It has tall straw, and large heavy grain.

—The great northern rye very nearly resembles the Tyrolese giant rye; and affords a lofty and stiff straw, and a large, handsome, and heavy grain; but, even when sown in summer, does not tiller out more than the common English rye.—The Vierlande rye is also a very fine variety, conspicuous for its large and beautiful grain.—"Should the grain of rye be the cultivator's object, either for sale or for rearing or fattening cattle, the Tyrolese giant rye, the great northern rye, or the Russian broad-leaved rye, are better adapted for that purpose than the common rye or St. John's day rye."

The brittle rye, *Secale fragile*, was introduced to Britain from Tauria in 1816, and is regarded as a separate species. A variety of it, called perennial rye, has smaller seeds than the St. John's rye; and when sown in the beginning of April by Mr. Lawson of Edinburgh, showed no appearance of running to ear so late as December. Mr. Taunton, at one time, had this plant in his experiment ground; and thought it worthy of attention from its precocious habit, and from its promising early feed; and did not find it either backward or penurious in ripening its seed.

The eastern rye, *Secale orientale*, was introduced from the Levant in 1807; and is also regarded as a separate species; but is viewed by the distinguished Russian botanist Bieberstein as, not a rye, but a wheat. It has a biennial duration, and a height of about 3 feet, and a similar flowering-time to the common rye.

The composite rye, *Secale cereale compositum*, is set down in botanical systems as a variety of the common rye; but, if true to its name, it would seem to have a clustered spike like the composite or Smyrna or Egyptian wheat.

The Astracan rye lies shrouded in very provoking uncertainty. "For 30 years past," says Mr. Taunton, "has the author been vehemently desirous to obtain the rye of Astracan, reported by some writers to be the most beautiful grain that grows in the world; but all his endeavours have been fruitless; nor has he even been successful in ascertaining whether it be a real rye, and, if so, whether it be a species, or only a fine variety of *Secale cereale;* or whether it be, as some have surmised, merely the Polish wheat, *Triticum Polonicum*, a very remarkable and beautiful grain, which the writer has heretofore raised and admired."

The Cultivation of Rye.—The soils most suitable for all or any of the kinds of rye are such as contain a large proportion of silicious matter. Light sandy soils, totally unsuitable for wheat, are peculiarly favourable for rye; soils containing a considerable intermixture of argillaceous earth are moderately favourable; and calcareous soils, such as those of the chalk downs, are by no means suitable.

The quantity of seed for a crop of grain need not be more than one bushel per acre, on good land and at midsummer sowing, for the St. John's day rye; but must range from 2½ to 3 bushels, in ordinary circumstances, at respectively autumnal and vernal sowings, for the winter and the spring ryes. The quantity, in the latter cases, for straw-plait, however, should be more than doubled; and even the quantity of St. John's day rye, and of the kindred varieties, when intended chiefly for green food, may be advantageously increased. Rolling after sowing, particularly on very light land, is indispensable. "The wire-worm," remarks Mr. Taunton, "feeds greedily on the St. John's day rye; and I have found it to destroy an entire crop when the ground has been left hollow. Indeed, I consider abundant compression of the new sown soil by Crosskill's clod-crusher, or, in its absence, by other heavy rollers, and by the treading of sheep, to be most efficacious, if not essential, to the success of this crop."

The growing of rye in mixture with wheat, in the manner of the ancient meslin, is still occasionally to be seen in Britain, particularly in the north of England; but this is a bad practice, both because the two grains may not always happen to ripen together, and because land which is rich enough to produce wheat should not be employed for a less valuable grain. "The common rye is also used by unskilful persons to sow amongst winter tares or vetches, in order to support them, that they may not, by trailing on the ground, exclude the light and air and become yellow and lose their lower foliage. But it is ill suited to this end, because it grows so much faster than the vetches, that when the vetches are cut in blossom, the rye is become hard and has ceased to be eatable, consequently is wasted. Moreover, it grows so much faster than the vetches that it overtops, and, if the proportion of rye be large, it, by reason thereof, shades and injures them. The proper grain to use for supporting winter vetches is wheat; and for this purpose the sturdiest varieties of wheat are the best. By a beautiful adaptation of the means to the end, wheat grows exactly as fast as the vetches do, and no faster, and has exactly the degree of stiffness requisite to support them; and when they are to be consumed, the whole mass is eatable together, the wheat being the most nutritious and valuable part thereof."

The general management of rye culture is, in all respects, the same as that of wheat; and any peculiarities which arise from speciality of object or of circumstances, have been incidentally mentioned in our account of the several varieties. A very peculiar disease to which rye is subject, requires to be well-known, on account of its terrible effects when the grain affected by it happens to be used as human food. See the article Ergot.

The Uses of Rye.—The grain of rye, as a bread-corn, is regarded as of the utmost importance in the domestic economy of very many districts of Continental Europe. Bread made from it con-

tains a less quantity of nutritious matter than that made from wheat, and is commonly accounted slower of digestion; yet it keeps longer, and is thought by the Continental peasantry to contribute better to the maintenance of muscular strength, and is preferred by labourers in harvest-work and in other sevère labour. Rye grain, next to wheat, is certainly the most nutritive substance for bread; and it constitutes the only bread-stuff of many a high and poor region where the soil and the climate are unsuited to the growth of wheat. It is also used extensively, throughout the Continent, in both the brewery and the distillery.

Various mixtures of rye grain and other substances are excellent food for the rearing and fattening of the domestic animals. Bruised or coarsely ground rye, in Belgium and Germany and other parts of the Continent, is mixed with bruised or coarsely ground barley, oats, beans, pease, or tares, and formed into a kind of coarse bread for feeding domestic animals, particularly horses; and a similar compound is employed for fattening oxen. A mixture of rye-meal and skim-milk, with a small proportion of ground gold of pleasure, has been used, with signal success in Britain, in the rearing of calves.

The value of rye herbage as early spring-food for ewes and lambs and milch-cows, and to be cut green, after it has thrown up its culm, for soiling horses in the stable, has been incidentally noticed, with sufficient fulness, in our account of the varieties. The common winter rye, however, must be understood as but very imperfectly adapted to these uses; for it tillers badly, and affords comparatively small bulk of forage; and in a few days after it has put forth its culm, it becomes hard and sticky, and is rejected by the animals, and can no longer, without great waste, be employed in soiling. But the St. John's day rye, and Cooper's early rye, besides being naturally profuse in herbage, and constitutionally slow to pass out of their succulent condition, have the high advantage—though that, perhaps, is more or less shared by all the other varieties—of being peculiarly susceptible of excitement and luxuriant increase by irrigation.

The usefulness of the straw of the common winter rye for the manufacture of straw-plait has already been incidentally noticed. But the long straw of well-grown St. John's day rye has also its peculiar uses. When this straw is, as it may always be, of 6 or even 7 feet in length, it is well adapted for thatching, and for making reed-screens for garden use in places where marsh reeds are not easily to be had; and it possesses peculiar value for the purposes of collar-makers, since one length of it suffices to go entirely round the deepest collar, even for the largest stallion; and it has been currently sold for these latter purposes by Mr. Taunton, at what he calls "the comfortable price of £5 per ton."

One other useful quality of St. John's day rye, when cultivated for soiling, is the following:—"If it has been sown on deeply ploughed and friable ground, when the land comes to be ploughed up for turnips, it will be found that the stubble of each plant has attached to it a huge tuft of long fibres, retaining a considerable quantity of fine mould entangled between the fibres. After dragging and harrowing, if these be carted off, they will furnish an immense supply of dry absorbent matter for the bases and liquid ingredients of manure-heaps, or for bedding the yards. Indeed, it would be, in some instances, impracticable to drill turnips on land without removing them; so that unless the farmer resorts to the barbarism of burning so large a mass of useful vegetable matter, he is compelled to prepare for an economical management of his next dung-heap, whether he will or no."

The produce of rye per acre is estimated by Boussingault at 26 bushels, and by Burger and the author of British Husbandry at 25 bushels. The average proportion of grain to straw is stated by Boussingault to be as 45 to 100, and by Burger and Schwertz to be as 41½ to 100. According to Boussingault, one part of rye grain, when dried at 230° Fahrenheit, was reduced to 0·834, and, when incinerated, left 0·0237 of ash; one part of rye straw, when completely dried, was reduced to 0·813, and, when incinerated, left 0·0368 of ash; the grain consists of 46·35 per cent. of carbon, 5·38 of hydrogen, 44·21 of oxygen, 1·69 of nitrogen, and 2·37 of incombustible matter, and the straw consists of 49·88 per cent. of carbon, 5·58 of hydrogen, 40·56 of oxygen, 0·3 of nitrogen, and 3·68 of incombustible matter.—*Loudon's Hortus Britannicus.—Lawson's Agriculturalist's Manual.—Baxter's Agricultural Library.—Goodrich Smith's Economy of Farming.—Parmentier's Traité Sur La Culture Des Grains.—The Museum Rusticum.—Boussingault's Rural Economy.—Low's Elements of Agriculture.—Hunter's Georgical Essays.—Radcliff's Agriculture of Flanders.—Reports to the Board of Agriculture.—Miller's Gardener's Dictionary.—Von Thaer's Principes Raisonnés d'Agriculture.—The Quarterly Journal of Agriculture.—Papers by Messrs. Taunton, Pusey, and Baker in the Journal of the R. Agricultural Society.*

RYEGRASS. The agricultural species and varieties of the gramineous genus *Lolium*. A statement of their generic characters is given in the article Lolium; and ample notices of their economical value and uses, and of the methods of cultivating them for all ordinary purposes, are contained in the articles Grasses, Clover, Hay, After-grass, and Rotation of Crops; so that, in the present article, we need only to describe them, and to state how they may best be cultivated for the raising of seeds.

The common ryegrass, *Lolium perenne*, grows wild in the grass lands of Britain, and has been more extensively cultivated by British

farmers than any other kind of forage grass. Its root is fibrous; its culm is normally about 20 inches high; and its spikelets are beardless, and longer than the glumes. It is eminently fitted, by the fibrous structure of its roots, for the purposes of the alternate husbandry; it possesses adaptation to a great variety of soils; and it offers great facility of propagation by the profusion in which it produces seeds, and by the uniformity with which it ripens them;—and, in the strength of these properties, it has acquired, and possibly may long maintain, a far higher place in the estimation of British cultivators than it is fairly entitled to, either on the ground of its intrinsic worth as a nutritive grass, or in comparison with some other bulkier or more nutritious or better compensating herbage plants. It is exceedingly little known in North America; and though partially tried in Canada and the Northern States by emigrants from Britain, it has been found rather too tender to withstand the rigorous cold of their winters. It is scarcely known, also, in the South of Europe, or even in the South of France, and has been generally supposed unsuitable to any climate which has a hot and droughty summer; and it has not very long commanded the attention of farmers even in the north of France, but is now pretty generally cultivated there as a plant of acknowledged utility.

The varieties of the common ryegrass are numerous. A few produce a comparatively small quantity of root-leaves and a comparatively large number of culms, and usually flower and seed and perish in their second year, and are popularly termed annual ryegrasses; and the rest produce a comparatively large quantity of root-leaves and a comparatively small number of culms, and originally possessed, or have been generally believed to possess, a constitutional capacity of maintaining themselves through a series of years, and are popularly termed perennial ryegrasses. But the so-called annual sorts are seldom less than biennial, and may sometimes, by good management and on good soils, be rendered triennial; while some of the most permanent of the perennial varieties, or such as are most capable of reproducing themselves in their true or distinctive characters from seed, are reduced by unfavourable circumstances to a duration scarcely longer than that of some real annual plants; and others have been so changed in both characters and habits, by the influence of continual culture and of adverse soils, as to have lost almost all traces of the favourable properties by which they were originally distinguished. No means exist of distinguishing the annual or biennial kinds from the perennial ones by their seeds alone; and when farmers intend to have plants of more than biennial duration, and cannot rely on the characters of the crop whence they gather their seeds, they ought to refuse seeds from plants sown in the preceding year, and to save them only from vigorous, close, and freely-seeding plants of at least two years' standing.

The annual ryegrass is the only one of the biennial ryegrasses in ordinary cultivation. Its culms, besides being more numerous than those of the perennial varieties, are rather taller and have a smaller proportion of foliage. It has been commonly supposed, from the greater number and height of its culms, to yield a greater bulk of herbage in the first year than any of the perennial varieties, and therefore to be fitter for single crops of hay; but it makes a wirier and less palateable hay than these varieties, and is sadly deficient in bulk of root and of cauline foliage, and really possesses no peculiar good property whatever except the doubtful one of yielding a comparatively large produce of seeds. Most or all of its bad properties, too, as well as its merely biennial duration, are liable to be shared by plants raised from the seeds of the first year's crop of any reputedly perennial variety.

Whitworth's ryegrass, was introduced by G. Whitworth, Esq., of Acre House, in Lincolnshire, who, in 1823, had 60 varieties of ryegrass under experiment. It eminently possesses the properties of both early and late growth; and has so remarkably fine foliage as to adapt it well for mixtures of lawn grasses; and is so very vivacious, or takes so enduring a hold of the soil, that two or three ploughings are requisite to prevent it from springing out of a broken up lea, and injuring a succeeding crop.

Pacey's ryegrass occurs naturally in some rich meadow lands; and was introduced to notice by Mr. Pacey, a cultivator in the higher districts of Staffordshire; and was regarded by Sinclair as the most valuable of all the ryegrasses with which he was acquainted. Its root-leaves are numerous and large; its cauline leaves are long, yet have not so fine an appearance as those of Whitworth's ryegrass; and its spikelets are shorter, and contain fewer seeds, than those of most other varieties. This ryegrass is well adapted both for pleasure-grounds and for permanent pasture.

The compound ryegrass, or broad-spiked ryegrass, occurs naturally among long under-grass, on rich soils, principally in cart-tracts and other partially beaten parts. It has a short broad spike, crowded at the top with spikelets.—The Devonshire evergreen ryegrass, or Devon Evers, is remarkable for vigorously withstanding the severities of winter, and thence takes its name of evergreen; but does not yield so large a crop as some of the other varieties.

Russell's ryegrass was first cultivated by the late Mr. Holditch, Editor of the Farmer's Journal; and was named in honour of the Duke of Bedford, who pointed out, in a rich fen pasture, the plant whence the original seeds of it were obtained. It grows earlier in spring, remains later in autumn, has a much stronger habit of growth, and yields a greater bulk of pro-

duce, than either Whitworth's or Pacey's varieties.

The Church-bennet or Church-bent ryegrass is an excellent variety, cultivated in some parts of Berkshire.—Molle's ryegrass is a favourite variety in some districts; and though of a rather slender habit, grows tall, and yields a very bulky produce.—Stickney's ryegrass was introduced by Mr. Stickney of Holderness; and resembles Molle's in habit; but is stronger, more enduring, and both earlier and later.—Pollexfen's ryegrass was raised by Mr. Pollexfen of Kirkwall in Orkney; and resembles Stickney's; but has a darker green colour.

Seven pretty distinct varieties of ryegrass, which have received botanical designations, are described almost well enough by their mere names,—the more so as their peculiar characters possess far more interest for the mere botanist than for the farmer. These varieties are the slender, *L. p. tenue*, an inhabitant of dry impoverished pasture land; the humble, *L. p. humile*, only 6 or 7 inches high; the branchy, *L. p. ramosum;* the paniculate, *L. p. paniculatum;* the many-flowered, *L. p. multiflorum;* the monstrous, *L. p. monstrosum;* and the viviparous, *L. p. viviparum.*

The spreading ryegrass is remarkably stoloniferous, and differs very evidently from a stoloniferous variety mentioned by Sinclair, and is probably entitled to rank as a separate species, under the name of *Lolium stoloniferum.* Messrs. Lawson obtained seeds of it from Germany, and notice it as follows in their Agriculturalist's Manual:—"It was about a fortnight longer in running to seed in the nursery than any of the other varieties of ryegrass, and produced comparatively few flower-stalks. It is of early spring growth, pushing out long prostrate stolons or shoots, with an abundance of foliage, so that one plant, by the time the spikes begin to appear, will form a close tuft, extending from 2 to 3 feet in diameter. These shoots, however, although lying on the ground, never attempted to strike root until near the end of the season, and even then very sparingly. Entire height about 15 or 18 inches from the surface; but the length from the root to the point of the spike is often nearly 3 feet; spike long and slender; spikelets remote, small, and few seeded."

The thick-stalked ryegrass is noticed as follows in the same work:—"This variety was procured from Vilmorin & Co., Paris, under the name of *Lolium grossum.* It is nearly as remarkable for its stiff and upright habit of growth as the last is for its slender stoloniferous habit. Height about 20 inches; spike about 8 inches long, and very broad; spikelets, which are very long, placed so that the point of the one reaches to the base of the next above, containing each 8 or 10 seeds. The plants do not seem to grow freely in the beginning, but stand well out in the end of the season."

The Italian ryegrass, *Lolium italicum*, is regarded by some persons as a wide variety of the common ryegrass, and by others as a separate species. It is much more nearly allied to Stickney's ryegrass than to any other variety of the common ryegrass; but it is not so luxuriant, and it has always an awn or beard on its lower paleæ. One kind of it has an upright stem, a pale-coloured young herbage, and a comparatively long awn, almost like a tail; and another kind has a more fibrous root, a dark-coloured spreading stem, and a comparatively short awn. The Italian ryegrass has long been cultivated in Italy and in some other parts of Continental Europe; but it did not become known as a field-plant in Britain till within the last 15 or 18 years. It has a stronger braird than any of the varieties of the common ryegrass,—arrives sooner at maturity,—has taller and more upright culms, broader and lighter-green leaves, more abundant foliage, longer spikes, more thinly set spikelets, and a smaller size and less bulky produce of seeds. It is preferred by cattle to any of the common ryegrasses; and is greedily eaten by them, whether in its green or in its dry state. Its seeds are little more than half the weight, bulk for bulk, of those of any of the common ryegrasses raised under the same conditions of soil and culture. It is better fitted for being grown alone than in mixture with clover, lucern, or other herbage plants; for it grows so rapidly as to be liable to choke them. It has eminent adaptation to the production of only one year of grass; and though rushing speedily up to maturity, and though far more truly a biennial plant than a perennial one, yet when cut down before flowering, it is often of several years' duration. It may be sown in either spring or autumn; and if sown by itself in the latter, at the rate of from 16 to 18 lb. per acre, and properly rolled in, it will render the turf of the following autumn like that of an old meadow, and will yield more than a double crop in the following year. It has, indeed, been denounced by some farmers as a much less favourable preparation than the other ryegrasses for wheat or any other succeeding crop; but, if due attention be paid to the selection of its most suitable variety, it will be found almost or altogether as good a preparation as any of them of the same duration as itself, and at the same time will excel them both in productiveness and in intrinsic value. Public opinion has erroneously pronounced the light-coloured and long-awned variety to be the only true plant, and the dark-coloured and short-awned variety to be more or less spurious; and when this error comes to be generally corrected, Italian ryegrass will probably acquire a great increase of reputation. "Having observed," says Mr. Rodwell of Alderton Hall, "in the growth of my crop reported on in the Royal Agricultural Society's Journal in the year 1841, some plants that were, as I supposed, not genuine, that is, not of the pale colour, nor pro-

ducing with long awns, I determined upon a fresh importation of seed direct from Italy, from which I have since tested the properties of the two varieties, both of which I have since cultivated with great care and attention; and I am now fully convinced, from every comparison I have made, not only of the different kinds of plants in different fields, but of both kinds in the same fields, and in every case have satisfactory proof that the best grass, namely, that which is the most productive and the most nutritive for all cattle, is the plant which spreads upon the ground, is dark-coloured, and being the produce of seed with short awn; and my conclusion has been more fully confirmed during the past week by testing the varieties, both in weight and bulk, finding that the dark-coloured plants from the seed of the short-awned grass exceed both in weight and bulk the pale-coloured plants by more than 30 per cent. It will be also worthy the observation of those who intend to cultivate this grass, that if intended as a biennial or a perennial grass, in that case the dark-coloured is much preferable to the pale-coloured grass, the former branching and becoming thicker, and the latter spindling up and thus becoming thinner in plant every succeeding year."

When ryegrass seed is wanted, either a crop may be raised expressly for the purpose, or the thickest part of a hay crop may be reserved at the hay-season, and allowed to stand till it go into seed. In either case, the seeding grass must be cut down when the seeds are nearly ripe, and not allowed to stand till they are quite ripe; and shortly after it is mown, it must be carefully lifted, and tied into bundles a little smaller than corn sheaves. The bands used for tying should be made either of the grass itself, or of hay twisted into ropes. The sheaves are then stooked in the same manner as corn, for the purpose of drying; after which the ground is carefully raked, and the hay thus collected made into small cocks. When the sheaves have become sufficiently dry, they may be carried to the stack-yard, and built in a small stack, well ventilated by means of a funnel up the centre, which admits a free current of air, the seed being thrashed out in spring and prepared for sowing. But the preferable practice is to separate the seed from the stalks as soon as the latter have become sufficiently dry for the purpose, both because the hay is rendered almost useless by being stacked up with the seed, and thrashed in spring when it is very brittle, and because the seed itself is more liable to heat in the stack than in the granary, where it can be noticed and turned over as often as necessary. The thrashing, which is always done with a light flail, may be performed in the field, and the hay made into cocks for further drying; or the ryegrass may be carted to the stackyard, and there thrashed on a strong door, placed upon a winnow cloth, similar to that used in rippling flax. The seed is then conveyed in sacks to the granary, and laid thinly on the floor to dry. It is to be regularly turned over at least once a day to prevent fermentation, the least degree of which would be fatal to the vegetative powers of the seed. When sufficiently dry, it may be winnowed, measured, again spread rather thickly on the granary floor, and protected from the depredations of vermin. The seed is again slightly winnowed in spring immediately before being required for use, to free it of dust and all impurities. When ryegrass is cultivated expressly for seed, from 25 to 30 bushels are often obtained per acre. The hay is of course of an inferior quality, and the land considerably exhausted in consequence of allowing the crop to mature its seeds.

RYELAND SHEEP. See Sheep.

S

SABAL. A genus of small, beautiful, tropical palms. Five species of it occur in the palm-houses of Britain. It is nearly allied to the genus Corypha. See the article Fan-Palm.

SABBATIA. A genus of ornamental, herbaceous plants, of the gentian family. Several species, principally biennials of from 6 to 15 inches in height, with red or purple flowers, have been introduced to Britain from North America; and will thrive on any common garden soil.

SACCHAROMETER. An instrument for ascertaining the proportion of sugar which any liquid contains. It is useful in brewing and wine-making and similar processes. A number of kinds of it, and also a number of substitutes for it, are in use. The practical point is simply to determine the specific gravity of the wort or other liquid.

SACCHARUM. The sugar cane genus of grasses. It belongs to the villiflorous tribe; but has a structure and habit similar to the reeds. About 10 or 12 species of it have been introduced, as curiosities, to the hothouse collections of Britain; and at least 20 other species are

known. Several of the species are cultivated, in various hot parts of the world, for the production of sugar; and a number are useful for reed-pens, for thatch, for railings, for rafts, and for other economical purposes.

The officinal species, or common sugar-cane, *Saccharum officinarum*, concentrates in itself the main interest of the genus, and affords, at the same time, a good specimen of the species. It is a native of the East Indies, the West Indies, and some of the tropical parts of Continental America; it was introduced to British gardens from India toward the close of the 16th century; it seems to have been first cultivated by the Spaniards in their country, and to have been carried back thence, as an economical plant, to the West Indies and Brazil; and it is now abundantly cultivated in the West Indies, in Persia, and on the islands and sea-boards of the Indian Ocean. The root is jointed; several stems rise from each root, and are jointed, and commonly attain a height of from 8 to 14 feet; a leaf springs from each cauline joint, and sheaths the stem up to the next joint, and there expands out to a length of 3 or 4 feet, with a narrowness proportionate to the shape of a blade of grass, and with thin and sharply toothed edges; the flowers grow in terminal panicles of two or three feet in length, and have thin florets enclosed in long flexuose down; and the seeds are oblong and pointed, and ripen in the valves of the flowers. In the West Indies, the plant is propagated from cuttings, and does not ripen in less than from 14 to 17 months, but is cut for making sugar between the 6th and the 13th month, when the culms are from 7 to 10 feet high, and have a smooth, dry, and brittle cuticle; and, in good, rich, permeable soil, it commonly yields five crops of shoots before requiring to be repropagated. In British hothouses, it is propagated from slips or suckers, and grown in pots, filled with rich garden earth, and plunged in a moderate hotbed of tanner's bark. See the article Sugar.

SACCOLABIUM. A genus of ornamental, tropical, epiphytous plants, of the orchis family. The name signifies "sack lip," and alludes to the form of the labellum. The pimpled species, *S. papillosum*, was the earliest known in Britain, and was introduced hither about 20 years ago from India; and it has a white spotted flower, and blooms in autumn. The gemmed species, *S. gemmatum*, was introduced 8 or 9 years later, and carries pink and white flowers in May, and possesses a high degree of beauty. Some other species have been introduced.

SACK. A large canvas bag for holding grain, pulse, small seeds, and other similar farm produce. A number of sacks, proportioned to the quantity of produce likely to be sent to market, ought to be kept ready for use, and in sound and clean condition, on every farm. They may be made, more or less strong, and of either plain or tweeled sacking, according to the particular purposes for which they are to be employed; and all should be marked with the initials of the owner or with the name of the farm. When any become wetted, they must be shaken and dried; or when dirtied with mud, they must be washed; or when holed, they must be patched or darned;—and all should be kept stored away in some dry airy place, such as upon ropes across the granary.

SACK-BARROW. See Barrow.

SACRED BEAN. See Nelumbium.

SADDLE. The artificial seat of a rider upon a mule's or horse's back. It should be so constructed as to combine comfort to the rider with ease to the horse. It ought to press only on the back, and on neither the spine nor the withers; it must make everywhere an uniform pressure, and must neither tilt forward upon the points nor jut backward upon the seat; and, when fully adjusted and fastened on the animal, it should have as large a free space beneath the pommel as will permit the introduction of the hand. If these matters, and some others which are well-known to all duly qualified saddlers, are not fully attended to in the construction of any saddle, not only discomfort to the rider but much suffering and serious disease to the horse may be the consequence.

SADDLE-BACKED. See Back.

SADDLE-GALL. See Gall.

SADDLE-GRAFTING. See Grafting.

SAFFLOWER. See Carthamus.

SAFFRON. The prepared stigmas of the *Crocus Sativus*. This plant grows wild in the meadows of some parts of England, and is commonly classed as indigenous, but probably was introduced at some remote period from Greece or Asia. Its root is perennial, and comprises a solid and depressed bulb; its flower is sessile on the bulb, and rises before the leaves on a long, slender, white tube, and has a rich violet or lilac colour, and blooms in September and October; its stigma is pendulous, odorous, and deeply three-cleft, and has a brilliant orange colour; and its leaves are linear, somewhat revolute, and have a deep rich green colour, veined with a white line along the centre, and are enclosed with the tube of the flower in a membranous sheath.

"For the preparation of the saffron, the flowers are gathered early in the morning, just as they begin to open. They are then spread upon a table, and the pistils are carefully picked out of the flower, they being the part containing the saffron; the rest of the flower is useless. They are then dried upon a portable kiln, of a peculiar construction, over which a hairy cloth is stretched, and over this several sheets of white paper are laid, upon which the wet saffron is spread between 2 and 3 inches thick. It is now covered with other sheets of paper; and over them is laid a coarse blanket 5 or 6 times doubled, which is pressed down with a board and large weight,

after the fire is lighted. The first heat is strong, in order to evaporate the moisture; after an hour, when it is formed into a cake, it is turned, and the same degree of heat continued for another hour. The fire is then reduced, and a moderate heat kept up for 24 hours, during which time the cake is frequently turned in order to dry it thoroughly; this having been accomplished, it is fit for the market." The finest saffron, however, consists simply of the dried stigmas, and is not formed into a cake, and bears the name of hay saffron.

The cultivation of the saffron crocus was practised in very ancient times. The Greeks and the Romans made use of saffron for perfuming halls and theatres, for scenting salves and balsams, and for seasoning dishes; and the latter people sent to the Levant for it in early times, before they had learned to cultivate it for themselves. The cultivation of it is supposed to have been introduced to England at the time of the Crusades; and was long carried on in Essex, particularly in the vicinity of Saffron-Walden, to which it gave its name; and was conducted also in Cambridgeshire, Herefordshire, and Suffolk, but eventually became confined to Stapleford. The saffron of the market is supplied from England, Sicily, France, and Spain. The English is the best; and the Spanish is the worst, being generally injured with oil in which it has been dipped to ensure its keeping. But all cake saffron is occasionally or even often adulterated with intermixtures of the fibres of dried beef, or of the petals of the safflower, the golden thistle, and the common marigold; and it may be tested by infusing a piece in hot water, when the true saffron or expanded stigmas will become easily distinguishable from the intermixed ingredients.

The soil most suitable for the cultivation of saffron is rather rich and of medium texture. The bulbs should be planted in June, at distances of 6 inches from row to row, and of 3 inches from bulb to bulb; and the crops are taken, year after year, simply by gathering the flowers when they expand. One plantation should generally stand for three years; and, at the end of that time, the bulbs should be taken up, and a new plantation formed. Miller computes the average produce per acre of dried saffron, at about 2 lbs. for the first year, and 24 lbs. for the two subsequent years, — the quantity in the third, however, being considerably greater than that in the second.

Saffron is used both in medicine and as a dye. It has a sweetish penetrating odour, a bitterish warm taste, and a rich, deep, red orange colour. It acts as a stimulant and antispasmodic, but is liable, in large doses, to produce convulsive laughter and some dismal consequences; and is seldom given, in modern practice, except as a qualifying principle of other medicines. The colouring principle of it is soluble in water and alcohol, and is of itself a bright yellow, but becomes first blue and then lilac by the action of sulphuric acid, and green on the addition of nitric acid; and in allusion to the great diversity of tints which it assumes under different circumstances, it has been called Polychroite.

SAFFRON (Bastard). See Carthamus.

SAFFRON (Meadow). See Colchicum.

SAGE,—botanically *Salvia Officinalis*. A hardy, evergreen, economical undershrub, of the labiate order. It is a native of the south of Europe, and was introduced to Britain toward the close of the 16th century. Its stem is quadrangular, branching, bushy, and from 12 to 24 inches high; its younger branches are whitish and downy; its leaves stand in pairs on footstalks, and are ovate-lanceolate, crenate, wrinkled, and sometimes of a reddish or purplish tint; and its flowers grow in six-flowered distant whorls, on long terminal spikes, and have a fine blue colour, variegated with white and purple, and bloom in June and July. Some of the chief of many varieties of this plant are the common or red,—the green,—the small-leaved green,—the broad-leaved or balsamic,—the wormwood,—the green, with variegated leaves,—the red, with variegated leaves,—the Spanish or lavender-leaved,—and the painted or party-coloured.

Sage was formerly in extensive use and high reputation as a medicinal plant; and it still holds a place in the Edinburgh pharmacopœia, and in works on medical botany, as a stimulating carminative, and slightly astringent drug; but it has quite lost the confidence of intelligent practitioners, except merely for making a grateful tea, in cases of great nausea, during febrile complaints. It continues, however, to be cultivated in the kitchen garden as an aromatic plant, and for flavouring various dishes. It loves a dry and moderately fertile soil, in a rather sheltered situation; and may be propagated from slips or cuttings, planted in May or June, in dibble-rows, at distances of 6 inches from row to row and from plant to plant. Only the outer and strongest shoots should be taken for cuttings; and the plants, from the time of their becoming fit for use, should be so kept and gathered from as always to have regular bushy heads.

SAGE (Jerusalem). See Phlomis.

SAGITTARIA. See Arrow-head.

SAGAPENUM. A medicinal gum, imported from the Levant. The plant which yields it is supposed to be a ferula; but is not certainly known. The gum has a taste and odour similar to asafœtida, but weaker; and occurs in agglutinated drops or masses, which have a slight translucency, a brownish yellow colour, and a horny fracture. It possesses antispasmodic and emmenagogue properties; and is sometimes administered in the same sort of cases as asafœtida, but does not at all equal that drug in power.

SAGO. The farinaceous pith of a number of endogenous tropical trees. These trees are most plentiful in the islands of the Indian Archipel-

ago; and constitute great forests in the Isle of Ceram; and particularly abound in all the islands which are most favourable to the growth of the clove and the nutmeg trees. The chief species is the *Sagus Rumphii* or *Metroxylon Sagus*, called by the natives the Libby-tree or Libley-tree, a palm of commonly from 30 to 50 feet in height. This tree grows at first very slowly, and has a spinous or thorny armature; but it afterwards grows with great rapidity, and soon attains its full height, and throws off its armature, and acquires a girth of 5 or 6 feet. The exterior part of its trunk is a hard, ligneous tube or cylinder of about 2 inches in thickness; and the interior part, or everything enclosed within the tubular shell, is a farinaceous pith, intermixed with numerous longitudinal fibres. The tree is known to be mature by the transpiration of a whitish dust through the pores of the leaves; and it is then felled, and cut into lengths of 5 or 6 feet. The woody part of one side of each piece is sliced off; a sufficient quantity of the longitudinal fibres and the pith at each end is left to let the whole piece have the form of a trough; all the rest of the interior is cut out; portion after portion of this is returned into the trough, in mixture with water, and there beaten with a spatula or piece of wood; the flour or farinaceous matter has a greater specific gravity than the fibres, and after being separated from them by this beating, is allowed to subside; the water and the floating fibres are then poured off; and the pulp is finally washed several times with clean water, and either granulated by being forced, in a half-dried state, through a kind of funnel, or variously dried and bleached and made to acquire a pearly lustre by means of artificial heat and of warm sifting and half-baking. One tree produces from 2 to 4 cwt. of flour.

The *Sagus Rumphii* was introduced to the palm-houses of Britain, about 48 years ago, from India; and three other palms, constituting with it the genus *Sagus*, or popularly the Sago-Palm genus, were introduced about 20 years later,—the wine-bearing, *S. vinifera*, from Guinea,—and the Ruffia and the pedunculate, *S. ruffia* and *S. pedunculata*, from Madagascar. But sago, similar to that of the *Sagus Rumphii*, is obtained also from the *Saguerus Rumphii*, the *Corypha umbraculifera*, the *Caryota urens*, the *Phœnix farinifera*, and some other palms; and a coarse sago is obtained from the several species of the non-palmaceous cycadeæ. See the article Cycas.

The common sago of commerce has a variable character, and sells much cheaper than the pearl sago, and may easily be imitated by a preparation of potato starch. See the article Potato. Much of the sago of the shops, previous to the removal of the enormous duty which was formerly exacted on its importation, was either partially or wholly adulterated. Pearl sago is a comparatively recent manufacture of the Chinese, and seems to hold some such relation to common sago as refined sugar does to raw sugar. The importation of sago into Britain amounted to only 1,339 cwt. in 1822; and rose to 3,859 cwt. in 1832; and afterwards became so great as to render sago a British bread-stuff, and even an available commodity for the feeding of farm stock.

Sago is the staff of life in the Molucca Islands; and is highly valued as an article of food, for both the sick and the strong, in India. It is but moderately nutritious, consisting chiefly of starch; yet it forms a grateful jelly, and makes an excellent pudding, and combines with three times its weight of wheaten flour to make a palatable, wholesome, and keepable bread. It has long been known, in Britain, as a suitable aliment for infants and for convalescents from acute diseases; and it has been proved, within the last 12 or 15 years, to be admirably adapted for calves, while on milk,—for cows, some time before and after calving,—for young horses in winter, as a substitute for dry corn,—and for young pet lambs, whose mothers have either died or forsaken them. It seems, also, well suited to sporting dogs and to fast-working horses, since it does not affect the wind; and it might be advantageously employed, in all departments of the poultry-yard, as a means of rendering the flesh of fowls more white and delicate for the table. It is commonly used in the state of a jelly; and can easily be reduced to that state with boiling water; but it must either be diluted to the thinness of a drink, or mixed with other ingredients, or beaten up to a comparatively solid consistency, according to the species and the condition of the animals to whom it is given. To a horse after a severe run or burst in the field, about a pound of jelly may be given in complete solution in two or three gallons of warm water; and this will prove a most grateful and refreshing drink. To milch cows, it may also be given dissolved in water as a drink; and it will probably help to give their milk a kernelly flavour. To calves it may be given, in mixture with new milk, as food, in the same proportion as the jelly of lythax or linseed porridge. To pigs, it may be given in drinks, to the amount of two or three pounds to each pig once a-day. To fowls, it should be given in combination with barley-meal, in the form of warm balls. And to dogs, it may be given in the combination of half a pound of sago, boiled to a jelly, and poured over biscuit, bread, or potatoes, previously soaked in milk, and now all beat up in the form of a jelly.

SAINFOIN, or Saintfoin,—botanically *Onobrychis*. A genus of ornamental plants, of the hedysarum division of the leguminous order. It has a five-toothed or parted calyx, and a one-celled, one-podded, thick-skinned, rough-surfaced, crested or winged pod. One species grows wild in Britain; about 20 species have been introduced from other countries; and nearly 20 more are known. Two of the introduced species are

hardy annuals; nearly all the others are hardy, erect, perennial-rooted herbs; and most have a height of about a foot, and carry either purple, pink, yellow, or white flowers.

The indigenous or cultivated species, *Onobrychis sativa*, called by Linnæus *Hedysarum onobrychis*, concentrates in itself the main interest of the genus, and commonly makes a complete monopoly of the name, and at the same time occupies the rank of an important agricultural plant. It grows naturally on light chalky soils in various parts of England; yet is said to have been originally introduced as an agricultural plant from France. It formerly bore the popular English name of cock's head; but is now known among farmers only by its French name of sainfoin or saintfoin, signifying "holy hay." Its roots are subfusiform and perennial, and are capable of penetrating to a very great depth; its stems are recumbent, yet not far from upright, and have commonly a length of two or three feet; its leaves are pinnate and smooth; its leaflets amount to from 9 to 15 on each leaf, and are opposite and acute; its flower-stalks are axillary, ascending, and longer than the leaves; its flowers grow in dense tapering spikes at the top of the flower-stalks, and have a beautiful variegated pink colour, and bloom in June and July; the wings of the flowers are about as long as the calyx; and the pods are erect and toothed at the margin and ribs. A variety called *O. s. bifera* grows faster and blooms earlier than the normal plant.

Sainfoin has long been cultivated in France and other parts of Continental Europe; and began to be cultivated in Britain about the middle of the 17th century; and is now regarded as the most valuable leguminous forage plant on the dry, thin, chalky and gravelly soils of the South of England, and as at the same time peculiarly suitable for poor, dry, non-gramineous soils of other districts. It chiefly serves for hay; and thrives well on lands which naturally yield little grass, and are not fit for being constantly under tillage. But, in most respects, it so closely resembles lucern, in at once nature, qualities, and treatment, that very little requires to be said respecting it different from what we have said respecting that plant. See the article Lucern.

Sainfoin requires a dry situation for its roots; and is fond of calcareous action; and has the power of sending down its rootlets, through rubble or through the crevices of rocks, to the depth of 15 or 20 feet, in search of sufficient support or nourishment; and cannot long thrive in any soil whose surface becomes matted or even considerably occupied with grasses or spreading weeds. It luxuriates on almost any dry chalky soil, or on any open and poor land which has a calcareous substratum, within a reachable depth; but will not thrive in mere sands or gravels, unless they receive a large artificial intermixture or dressing with lime; and has little or no repugnance to natural richness of soil, except in so far as the free ranging of its roots may be hindered, or the growth of grasses and weeds encouraged.

The preparation for sainfoin ought not to comprise any manuring, and should consist simply in thorough cleaning and in deep and minute pulverization. It comes very appropriately at the close of an alternate rotation of seven or eight crops; and it may be sown either broadcast or in drills,—either alone or with a corn crop, in the same manner as the clovers and grasses. The broadcast sowing is preferable to the drilling. The seeds are large, and require to be more deeply covered than those of clover, and may be ploughed in with a very shallow furrow. About four bushels per acre are required for broadcast sowing; and about three for drilling. A sowing with barley or other grain, to about half the amount of seed which would be requisite for a full crop of it, is much better than sowing the sainfoin alone; for the corn shades the sainfoin and keeps it moist during the first summer, and at the same time is not thick enough to injure it by a crowding of the soil or by an undue abstraction of nourishment. When broadcast sowing is preferred, the corn should be sown first, and once harrowed, and the sainfoin sown after and lightly rolled; and when drill-sowing is preferred, the drills for the corn should run in one direction, and those for the sainfoin in a cross direction or at right angles.

Sainfoin attains its full growth in about three years, and usually begins to decline on sandy or gravelly soils in seven or eight years, and on chalky soils in from eight to ten years. But though thenceforth losing vigour, it has been known, in a neglected state, to exist 50 years, and even nearly 100 years. It may also be prolonged in vigour, and likewise rendered increasingly luxuriant in its earlier years, by the judicious application of suitable top-dressings. On deep loamy soils, along the skirts of chalk hills, indeed, no top-dressing should be given; but on thinner and poorer and colder soils, a top-dressing of 5 bushels per acre of gypsum, or of 10 or 12 bushels of peat ashes, or of 30 bushels of coal ashes, once a-year or once in two years, according to circumstances, will generally prove highly beneficial. The grand enemies to the duration of sainfoin are the grasses and the creeping weeds, which form a close turf and choke up the crop; but these cannot be controlled any further than by the selection of a soil which is naturally unfavourable to them, or by the hoeing of a drilled crop in the next season after sowing.

Sainfoin makes excellent hay; and is chiefly valued for that purpose. It should be cut when in full bloom, and so managed as to retain, in its dried state, the natural hue and form of the flowers, and the clear full verdure of the stems and the leaves. It is treated, in a general way, in the same manner as other hay plants; but it requires very particular care, and is specially

susceptible of injury from humidity in the atmosphere, and may both lose all its fragrance and be rendered exceedingly difficult to dry by a drenching rain. A cutting of it upon any thin calcareous soil, is generally both richer in quality and greater in quantity than a first cutting of clover. But it seldom admits of being profitably cut a second time in one year; and the after-grass of it is commonly depastured by horses and cattle. Sheep have a keen relish for it; but, in consequence of their eating it very closely down, they must not have access to it at a late period of the year, lest they should leave its root-crowns too bare to resist the killing action of the winter's frost.

Sainfoin plants intended for seed should remain untouched till their husks become somewhat brownish, and their seeds become quite plump and firm; and, as they ripen very unequally, and are exceedingly ready to shed their seeds, they should be cut while the dew is on them, and not turned or touched in the swathes, if possible, till they become sufficiently dry; and they may then be either thrashed out on cloths in the field, or carried away with all possible gentleness to a thrashing machine. The seeds, after being thrashed out and cleaned, should be spread closely upon a boarded floor, and left there till they become so thoroughly dry as to escape all risk of fermenting. The breaking up of sainfoin land may be effected by scuffling out the roots and weeds and afterwards burning them; but is more easily done by paring and burning. See the article Paring and Burning.

SAINFOIN,—botanically *Astragalus Onobrychis.* A beautiful, hardy, perennial-rooted, herbaceous plant, of the milk-vetch genus. It was introduced from Austria to Britain before the middle of the 17th century. Its stems are procumbent or trailing and about 20 inches long; and its flowers are densely capitate, and have a purple colour, and bloom in June and July. It forms the type of a subgenus of the milk-vetches.

SAINT BARNABY'S THISTLE. See Centaurea.

SAINT JOHN'S WORT. See Hypericum.

SAINT PETER'S WORT,—botanically *Symphoria.* A genus of hardy, ornamental, deciduous, North American shrubs, of the honeysuckle family. The glomerated species, *Symphoria glomerata,* called by Linnæus *Lonicera symphoricarpos,* is the type of the genus; and takes its botanical names from the clustered arrangement of its fruit. It is a native of Virgina and Carolina; and was introduced to Britain in 1730. It has commonly a height of about 4 feet. Its main stems are ragged, and have a dirty dark brown colour; its branches are numerous and generally short,—yet some are slender, trailing, and long; its leaves are very numerous, oval, and about half an inch long, and stand opposite on exceedingly short footstalks, and constitute an aggregate rich foliage, and die away in autumn to a dark-brown colour; and its flowers grow round the stalks, and are small and inconspicuous, and bloom in August and September. A variety occurs with variegated leaves. Four or five other species, all similar in height to the glomerated, have been introduced.—St. Peter's wort is also the popular name of a hardy, perennial-rooted, yellow-flowered, herbaceous species of hypericum.

SAL AMMONIAC. The muriate of ammonia. It is a product of volcanoes; and was formerly imported to Europe from Egypt, where it was obtained by sublimation from the soot of camel's dung; and is now manufactured in Britain and on the Continent by the mutually decomposing action of sulphate of ammonia and either muriate of soda or muriate of magnesia, and by other and preceding and widely different processes. It is commonly formed into hemispherical, whitish, elastic cakes, of about two inches in thickness. It has a pungent saline taste, but has not any smell. It has a specific gravity of 1·45; and slightly attracts moisture from the atmosphere; and is soluble in 3¼ times its own weight of water at 60° Fahrenheit; and sublimes at a high temperature, without melting or becoming changed. It consists of one equivalent of muriatic acid, and one equivalent of ammonia. This salt was formerly regarded as a powerful internal remedy in both human and veterinary medicine; but it is now scarcely ever used except externally and in mixture with other substances; and it acts principally as a refrigerant and a discutient. See the article Ammonia.

SALEP. See Orchis.

SALICARIA. See Lythrum.

SALICIN. A peculiar principle found in the bark of the aspen and of several species of willow. It was first discovered by M. Leroux, in 1830, in the bark of the *Salix helix.* It is separated by chemical reagency from a watery decoction; and it forms in perfectly white, delicate, acicular or prismatic crystals. It has a very bitter taste; and is sparingly soluble in cold water; and possesses neither acid nor alkaline properties; and consists of two equivalents of carbon, two of hydrogen, and one of oxygen. It has similar medicinal virtues to quinine.

SALICORNIA. See Glasswort.

SALISBURIA. An ornamental, hardy, deciduous, small tree, of the amentaceous order. It constitutes a genus of itself; and is specifically called *adiantifolia* or the maiden-hair-leaved. It has highly curious and very exotic-looking foliage; and, on that account, is entitled to a place on every lawn, and makes an interesting appearance in every collection of hardy shrubs. It is a native of Japan; and was introduced to Britain in 1754. It loves a soil of sandy loam; and is propagated from cuttings; and commonly attains a height of about 20 feet; and blooms in April and May.

SALIVA. The fluid secreted within the mouth of animals. It forms spittle, and is of main use

in keeping the mouth moist, and in softening and empulping food during mastication. It is secreted partly by the parotid gland, situated below and before the ear,—partly by the submaxillary glands, situated under the jaw,—partly by the sublingual glands, situated under the tongue,—and partly by a number of small glands, situated on every part of the mouth, cheek, and lips. These glands, especially the principal ones, bear the name of salivary glands; and are liable to inflammation and swelling from catarrh; and occasionally become the seat of concretions, consisting chiefly of carbonate of lime. Saliva contains about 99·3 per cent. of water, and 0·7 of very complicated and somewhat variable solid matter. The saliva of man contains very little carbonate of soda; but that of sheep contains so much, that it effervesces with acids. The solid matter of saliva, in general, contains a large proportion of muriate of potash, much smaller proportions of the sulphate, the carbonate, the acetate, and the sulphocyanate of potash, and a minute quantity of some animal principle which some chemists suppose to be osmazome.

SALIX. See Willow, Osier, and Sallow.

SALLENDERS. See Mallenders.

SALLOW. Species of willow which are not flexible like osiers, but which form rough bushes or large trees. A number of different kinds of sallows grow wild in the hedges, and moist grounds, and marshy woods of Britain; and are useful for various economical purposes, and afford material for making the best kind of charcoal. See the article Willow.

SALLOW-THORN. See Buck-Thorn (Sea).

SALMON,—*salmo salar*,—a celebrated fish belonging to the trout genus, which inhabits the northern seas, and ascends the rivers in spring for the purpose of depositing its spawn. The excellence of its flesh is well known, but it varies somewhat in different waters. In certain districts, the abundance of this fish forms a great source of wealth to the inhabitants, and it often forms a chief article of sustenance. The salmon inhabits the European coasts, from Spitzbergen to Western France, but is never seen in the Mediterranean. On the western shores of the Atlantic it is found from Greenland to the Hudson, but is exceedingly rare in the latter river, and never penetrates father south. It ascends the St. Lawrence to lake Ontario, and enters the tributaries of that lake; but the fall of Niagara presents a barrier to its further progress into the continent. In the North Pacific the salmon again makes its appearance, and frequents, in vast numbers, the rivers of North-western America, Kamtschatka, and Eastern Asia. A cold climate and clear water seem to be most congenial to its constitution. The salmon grows to the length of about four feet, and usually attains a weight of from 30 to 70 pounds. The body is elongated and compressed; the colour silvery-grey, with spots; the head of moderate size, and the upper jaw rather the longest. Almost all parts of the mouth, and even the tongue, are furnished with pointed teeth, as in the other trouts, and, like them, it has an adipose fin upon the lower part of the back. All the trouts are voracious and carnivorous, and in general seek the purest water. As soon as the ice melts, the salmon enters the mouths of rivers, and, as has been ascertained, almost always of those which gave them birth. They swim usually in immense bodies, in the middle of the stream, and near the surface: their progress is slow, and they make a great noise in sporting, if the weather be fine. They are easily frightened, either by a sudden noise or floating timber, and on such occasions sometimes turn aside from their course and return to the sea. When farther advanced, they make the most determined efforts to surmount rapids and cascades, and will leap a fall of twelve or fifteen feet in perpendicular height. If alarmed, they dart away with such rapidity that the eye can scarcely follow them. The velocity of this motion has been proved to equal twenty-five to thirty miles per hour. They penetrate far into the interior of the continents, and deposit their spawn in the lakes, &c., about the head-waters of the longest rivers. When the young are about a foot in length, they descend the rivers and take refuge in the ocean. Late in the following spring or in the beginning of summer, and after the old ones have ascended, the young again enter the rivers, and are then about eighteen inches in length. They again seek the ocean on the return of frosts. At two years old, the salmon weighs six or eight pounds; and it requires five or six years to attain the weight of ten or twelve. The salmon-fishery is one of the most important branches of business in the north of Europe. Immense quantities of this fish are taken every year, and form a considerable accession to the general mass of nutriment. The flesh is bright orange, but, though delicious to the taste, and very much sought after, is difficult of digestion.

SALPIGLOSSIS. A genus of ornamental, exotic plants, of the nightshade family. They first became known in Britain in 1824; and they came rapidly and generally into notice among all classes of florists. They are principally annuals of from 12 to 30 inches in height; and are remarkable for diversity of colour, and for a singular sportiveness and instability of character. Any single sowing, even without any attempt being made to intermix pollen, may produce many varieties in both shape and colour. Some of the kinds most generally esteemed—for whether they be species or varieties cannot easily be determined—are those called *S. picta*, *S. hybrida*, *S. atropurpurea*, *S. cærulea*, and *S. Barclayana*, the first two with violet flowers, and the others with respectively purple, blue, and yellow flowers.

SALPIXANTHA. A genus of ornamental,

exotic plants, of the acanthaceous order. The scarlet species, *S. coccinea*, was introduced a few years ago from Jamaica to the stoves of Britain; and is a low branching shrub, of very great beauty. Its leaves are opposite, peduncled, and ovate; and its flowers grow in loose, graceful, axillary, and terminal spikes, and stand out from them in opposite pairs, and have a tubular shape with expanding margin, and are scarlet without and white within, and bloom in autumn and the early part of winter.

SAL PRUNELLE. See NITRATES.

SALSAFY, or SALSIFY,—botanically *Tragopogon Porrifolius*. An ornamental, culinary, indigenous, biennial, herbaceous plant, of the goat's-beard genus, and of the succory division of the composite order. It grows wild in the moist meadows of some parts of England; and has long been cultivated in kitchen gardens. Its roots are long, white, and fleshy; its stems are smooth, tender, and about 4 feet high; its leaves are leek-like and comparatively broad; its calyx is longer than the florets or floral rays; and its flowers have a dull purple colour, and bloom in May and June. Its roots have a mild and sweetish flavour, and are boiled and eaten like carrots; and its young shoots are dressed and used in the manner of asparagus. It loves an open situation, and a deep soil of rich mould; and may be raised from seed sown at any time from March till May, either broadcast in beds, or in small drills 8 or 10 inches apart. The young plants, when 2 or 3 inches high, must be thinned out to distances of 6 inches; and the beds or drills must be occasionally watered. The roots will be fit for gathering from August till October; and the young shoots, in the following spring.

SALSILLA. See LILY (EATABLE ROOTED).

SALSOLA. See SALTWORT.

SALT. This term was originally employed to denote *common salt*, but was afterwards generalized by chemists, and employed by them in a very extensive and not very definite sense. They understood by it any body which is sapid, easily melted, soluble in water, and not combustible; or a class of substances midway between earths and water. Many disputes arose concerning what bodies ought to be comprehended under the designation, and what ought to be excluded. Acids and alkalies were allowed by all to be salts; but the difficulty was, to determine respecting earths and metals; for several of the earths possess all the properties which have been ascribed to salts, and the metals are capable of entering into combinations which possess saline properties. The old chemists, however, eventually restricted the term salt to three classes of bodies,—*acids, alkalies,* and the *compounds* which acids form with alkalies, earths, and metallic oxides. The salts of the first and second of these classes were called *simple salts;* and these of the third class were called *compound* or *neutral*. This last appellation originated from an opinion long entertained by chemists, that acids and alkalies, of which the salts are composed, were of a contrary nature, and that they counteracted one another; so that the resulting compounds possessed the properties neither of acids nor of alkalies, but properties intermediate between the two. The chemists of a later period restricted the term *salt* still more, by tacitly excluding acids and alkalies from the class of salts altogether; and the definition of it then came to be,—a definite compound of an acid and a base, each comprising at least two elementary substances; and though this definition excludes the whole group of what are called haloid-salts, and does not accord with the theories of some of the principal modern chemists, it is still, and perhaps will long continue, the most convenient for all popular and practical purposes.

The acid constituent of a salt may possess any degree of sourness, from an absolute negation of it up to the most mighty corrosiveness; and the basic constituent may be either an alkali, an alkaline earth, or a metallic oxide. Some salts, such as Epsom salt and Glauber's salt or sulphate of magnesia and sulphate of soda, are readily recognised by all persons as true salts; but others, such as marble, gypsum, bone earth, and flint glass, or carbonate of lime, sulphate of lime, phosphate of lime, and the double bisilicate of potash and bisilicate of lead, are thought by untutored observers to be totally different from salts. Yet the constitution of the latter is formed on exactly the same type as the former; bone earth, for example, being a compound of the corrosive oxygen acid of phosphorus and the earthy alkaline oxide of calcium, just as Epsom salt is a compound of the corrosive oxygen acid of sulphur and the earthy alkaline oxide of magnesium. Haloid salts, on the other hand, possess a truly salt-like appearance, but differ widely from all true salts in constitution; they comprise all the metallic chlorides, iodides, and fluorides, and are closely akin in nature to the oxides and the sulphurets; and they take for their type, the chloride of sodium or common salt, which consists merely of the two elements chlorine and sodium, and whose Greek name, together with a word signifying 'form,' furnishes the epithet haloid.

The new theory regards common salt as the type, not only of the haloid salts, but of all salts whatever; it views common salt as formed by the metal sodium taking the place of the hydrogen of hydrochloric acid; it supposes every acid to be ultimately or really a hydrogen one, and every salt of each acid to be formed by a metal taking the place of its hydrogen; and in order to make out its data, it ascribes all the oxygen of saline compounds to their acids, and denies that any of these acids are hydrates. In the case of the alkaline and the earthy sulphates, for example, it affirms that they contain, not the alkalies and the oxides themselves, but only their

respective metals; that they are formed, not by the alkalies and the oxides taking the place of the water of a hydrated sulphuric acid, but by the metals of these bodies taking the place of the hydrogen of a dry or anhydrous sulphuric acid; that they arise, not out of an acid compound of one equivalent of water and one equivalent of a body consisting of one atom of sulphur and three atoms of oxygen, but out of an acid compound of one equivalent of hydrogen and one equivalent of a body consisting of one atom of sulphur and four atoms of oxygen; and that, therefore, they differ from common salt only in having a compound radical, sulphur and oxygen, instead of the simple radical chlorine,—a body which, after all, may possibly prove to be as really a compound as the analogously acting body, cyanogen. "It may be stated," says Dr. Gregory, "that although the body consisting of one atom of sulphur and three atoms of oxygen exists, it is not truly an acid, and does not acquire acid properties until it has been in contact with water, and combined with it, that is, with hydrogen; that, with ammonia, this body does not form sulphate of ammonia, but an entirely different compound; that, although the supposed radical, consisting of one atom of sulphur and four atoms of oxygen, is unknown in a separate form, the same objection may be made to the older view in the case of nitric acid and many other acids,—for strong nitric acid is viewed as a hydrate of dry nitric acid, while dry nitric acid is quite unknown in a separate form; that those oxygen acids which exist without hydrogen, such as dry sulphuric acid, dry phosphoric acid, carbonic acid, silicic acid, and chromic acid, either have no acid properties till water is added, as in the case of dry sulphuric acid and dry phosphoric acid, or possess very feeble and ill-marked acid properties, as in the case of carbonic and silicic acids, which cannot neutralise the alkalies, and form with them an almost unlimited number of compounds; and that all those oxygen acids which possess in perfection the acid character, such as oil of vitriol, nitric acid, phosphoric acid in its active state, and the whole of the organic acids, invariably contain hydrogen in a form in which it is replaced by metals in the salts, or, according to the older view, water, which in the salts is replaced by metallic oxide. Now, as in water and metallic oxide, the oxygen is the same, it is, even on that view, hydrogen which is replaced by metal, when an acid is converted into a salt. It may be added, that considerations derived from the phenomena of galvanic decomposition, from the heat developed when bodies combine to form salts, and from the molecular or atomic volume of acids and salts, all concur to render it probable that oxygen acids are hydrogen compounds, not hydrates, and that oxygen salts contain a metal united to a radical, and not an oxide united to a dry or anhydrous acid."

The old theory, however, though less consistent and far less beautiful and less simple to the well-informed chemist than the new one, is really plainer and more useful to the farmer and the general thinker; it also figures exclusively in all the best chemical works down to a very recent period, and at the same time occupies a place by the side of the new theory in the formulæ of even the most recent chemical writings; and it has far too firm a hold of both the nomenclature and the discussions of general chemistry, whether in itself or in its connexions with agriculture, to be conveniently shaken off by any but complete adepts in chemical science. It likewise offers an easy rule for classifying all the true salts, according to either their base or their acid, or for readily comparing the saline combinations of each complicated acid, and those of each oxide and of each alkali, as well as those of each simple acid and those of each metal; and it conveniently leaves all other salts than the true ones to be arranged into the two supplemental groups of haloid salts and sulphur salts.

The groups of true salts, as arranged according to their acids, need not amount to more than six, and yet possess very distinct characters of classification. One group comprises the sulphates, sulphites, hyposulphates, and hyposulphites; a second comprises the nitrates, the nitrites, the chlorates, the iodates, and the bromates; a third comprises the phosphates, the pyrophosphates, the metaphosphates, the phosphites, the arseniates, and the arsenites; a fourth comprises the chromates, the borates, and the fluo-borates; a fifth comprises the carbonates; and a sixth comprises the hydrochlorates, the hydriodates, the hydrobromates, the hydrofluates, the hydrosulphates, the hydroselianates, the hydrocyanates, the ferrocyanates, and the sulphocyanates. Haloid salts, in addition to simple haloids, comprise acid haloids, each composed of a simple haloid and the acid of its radical, and also oxyhaloids, each composed of a simple haloid and an oxide of the same metal as its base. Sulphur salts are double sulphurets, and present a pretty close resemblance to true salts; and they have been classified into hydrosulphurets, carbo-sulphurets, arsenio-sulphurets, and molybdo-sulphurets. The total number of known salts amounts to several thousands; and the proportion of these which play a conspicuous part in the natural chemistry of the soil, and of manures, and of vegetation, and of the animal functions, is very great. Some salts combine with one another, so as to form double salts; and they may consist either of one acid and two bases, or of two acids and one base, or of two acids and two bases; but the great majority consist each of one acid and two bases.

The early names of the salts, so far as these bodies were known to chemists, were wholly destitute of scientific precision. At present, however, they are universally designated according to the nomenclature of Morveau. The name of each

salt consists mainly of two words, one generic, the other specific. The generic word precedes the specific, and is derived from the acid; the specific comes from the base. For example, a salt consisting of *sulphuric acid* and *soda*, is spoken of generically under the name of a *sulphate*, and specifically, by adding the name of the base; thus, *sulphate of potash*. The termination *ate* corresponds with the acid whose termination is in *ic*, and the termination *ite* with the acid whose termination is in *ous;* thus *sulphuric* acid gives *sulphates,—sulphurous* acid, *sulphites*. There are some acids containing less oxygen than those that terminate in *ous:* in such case, the word *hypo* is prefixed; thus we have *hypo*-sulphurous acid, *hypo*-nitrous acid, giving also salts that are called *hypo*-sulphites, and *hypo*-nitrites. When the salt is a compound of one atom, or proportional of acid with one of base, it is distinguished simply by the words denoting the acid and the base, without the addition of any prefix. If the salt contains *two* atoms of acid united to *one* atom of base, the Latin numeral adverb *bis* or *bi* is prefixed. Thus *bisulphate of potash* is a salt composed of two atoms sulphuric acid and one atom potash. Were there three, four, &c., atoms acid, the numeral adverbs *ter*, *quater*, &c., would be prefixed. Thus *quateroxalate of potash* means a compound of four atoms oxalic acid and one atom of potash. When two atoms of base are combined with one atom of acid, this is denoted by prefixing the Greek numeral adverb *dis*. Thus *diphosphate of potash* means a compound of two atoms potash with one atom phosphoric acid. The prefixes *tris*, *tetrakis*, &c., indicate three, four, &c., atoms of base with one atom of acid. Salts of this description were formerly termed *sub-salts;* at least in those instances where an alkaline reaction was produced upon test-liquors from the excess of base.

All salts, with a very few exceptions, are solid; and most either have naturally the form of crystals, or assume that form by the slow evaporation of their aqueous solutions. Some are soluble in water, and more or less sapid; and others are insoluble and completely insipid. One, the carbonate of ammonia, emits an exceedingly pungent odour, and has popularly the name of smelling salt; but almost all the others are totally odourless. Some have brilliant colours, and others have none; and some are transparent, others semipellucid, and others opaque. All which consist of a colourless acid and a colourless base, are themselves colourless; and some also which consist of a coloured acid or a coloured base are colourless; and many which consist of coloured constituents and are themselves coloured, possess entirely different colours from those of their constituents. Some have a powerful affinity for water, and attract so much moisture from the atmosphere as to deliquesce or become liquid; others remain unchanged under a dry atmosphere, but become moist under a humid one; and others show such indifference or resistance to water as to suffer no change from exposure to an atmosphere loaded with vapour. Some of the soluble salts dissolve in less than their own weight of water; and others do not dissolve in less than dozens or scores or even hundreds of times their own weight of water. Many salts, in the process of crystallizing, combine with themselves a definite portion of water, which is essential to their crystalline state, and bears the name of the water of crystallization; and some of these contain more than half of their own weight of this water, and yet are perfectly dry,—all lose the whole of their water when exposed to a strong heat,—and some, such as the sulphate of soda and the phosphate of soda, lose a portion of their water and crumble down into powder, or are said to effloresce, when merely exposed for some time to the air. Salts which do not take water freely into combination with their crystalline constitution, often enclose particles of it among the interstices of their crystals; and when heated, they are rent asunder by the expansion of these particles, and in consequence burst with a crackling noise, and are said to decrepitate. Several different salts which do not decompose one another may be held in solution by the same quantity of water which is merely sufficient to dissolve one; and, in some instances, two different salts, in consequence of their mutual combination, are soluble in less water than would suffice for the separate solution of either. Most salts produce cold during the process of solution; and those which contain water of crystallization produce more than those which contain none; and any produce more when dissolved rapidly and in large quantity than when dissolved slowly and in small quantity. All salts, either in a state of solution or in a merely moistened state, are decomposed by voltaic electricity.

The solubility of the soluble salts in water is one of their most important general properties. In this menstruum they are generally crystallized; and by its agency they are purified and separated from one another, in the inverse order of their solubility. The determination of the quantity of salt which water can dissolve, is not a very difficult process. It consists in saturating the water exactly with the salt, whose solubility we wish to know, at a determinate temperature, weighing out a certain quantity of that solution, evaporating it, and weighing the saline residue. We shall give the results of some experiments upon the solubility of a few salts.

Sulphate of Soda.

Temperature.	Salts soluble in 100 parts of water. Anhydrous.	Crystallized.
0·00°	5·02	12·17
11 67	10·12	26·38
17·91	16·73	48·28
28·76	37·35	161·53
30·75	43·05	215·77
32·73	50·65	322·12

40·15	48·78	291·44
50·40	46·82	262·35
59·79	45·42	
70·61	44·35	
84·42	42·96	
103·17	42.65	

Hence it appears that the solubility of sulphate of soda follows a very singular law. After having increased rapidly to about the temperature of 33°, where it is at its maximum, it diminishes to 103·17°; and at that point it is nearly the same as at 30·5°.

Solubility of Chloride of Potassium.

Temperature.	Salt dissolved in 100 water.
15·64°	43·50
49·31	55·63
74·89	65·51
105·48	77·89

Solubility of Chloride of Sodium (Common Salt).

Temperature.	Salt dissolved in 100 water.
13·89°	35·81
16·90	35·88
59·93	37·14
109·73	40·38

Solubility of Sulphate of Magnesia (Epsom Salt).

Temperature.	In 100 water.
14·58°	103·69
39·86	178 34
49·08	212·61
64·35	295·13
97·03	644·44

Solubility of Nitrate of Potash (Nitre).

Temperature.	Salt dissolved in 100 water.
0·00°	13 32
5·01	16·72
11·67	22·23
17·91	29·31
24·94	38·40
35·13	54·82
45·10	74·66
54·72	97·05
65·45	125·42
79·72	169·27
97·66	236·45

The action of salts on the animal organism is very diversified, and in most instances remarkable, and in many instances either mightily medicinal or powerfully poisonous. "Iodide of potassium, sulpho-cyanuret of potassium, ferrocyanuret of potassium, chlorate of potash, silicate of potash, and all salts with alkaline bases, when administered internally to man and animals in dilute solutions, or applied externally, may be again detected in the blood, sweat, chyle, gall, and splenic veins; but all of them are finally excreted from the body through the urinary passages. Each of these substances, in its transit, produces a peculiar disturbance in the organism—in other words, they exercise a medicinal action upon it, but they themselves suffer no decomposition. If any of these substances enter into combination with any part of the body, the union cannot be of a permanent kind; for their re-appearance in the urine shows that any compounds thus formed must have been again decomposed by the vital processes. Neutral citrates, acetates, and tartrates of the alkalies, suffer change in their passage through the organism. Their bases can indeed be detected in the urine, but the acids have entirely disappeared, and are replaced by carbonic acid which has united with the bases. The conversion of these salts of organic acids into carbonates, indicates that a considerable quantity of oxygen must have united with their elements; and there is no evidence presented by the organism itself, to which they have been administered, that any of its proper constituents have yielded so great a quantity of oxygen as is necessary for their conversion into carbonates; so that their oxidation can be ascribed only to the oxygen of the air. During the passage of these salts through the lungs, their acids take part in the peculiar process of eremacausis proceeding in that organ. A certain quantity of the oxygen gas inspired unites with their constituents, and converts their hydrogen into water, and their carbon into carbonic acid. Part of this latter product (1 or 2 equivalents) remains in combination with the alkaline base, forming a salt which suffers no further change by the process of oxidation; and it is this salt which is separated by the kidneys or liver. It is manifest that the presence of these organic salts in the blood must produce a change in the process of respiration. A part of the oxygen inspired, which usually combines with the constituents of the blood, must, when they are present, combine with their acids, and thus be prevented from performing its usual office. The immediate consequence of this must be the formation of arterial blood in less quantity, or in other words, the process of respiration must be retarded. Neutral acetates, tartrates, and citrates placed in contact with the air, and at the same time with animal or vegetable bodies in a state of eremacausis, produce exactly the same effects as we have described them to produce in the lungs. They participate in the process of decay, and are converted into carbonates just as in the living body. If impure solutions of these salts in water are left exposed to the air for any length of time, their acids are gradually decomposed, and at length entirely disappear. Free mineral acids, or organic acids without volatility, and salts of mineral acids with alkaline bases, completely arrest decay when added to decaying matter in sufficient quantity; and when their quantity is small, the process of decay is protracted and retarded. They produce in living bodies the same phenomena as the neutral organic salts, but their action depends upon a different cause. The absorption by the blood of a quantity of an inorganic salt sufficient to arrest the process of eremacausis in the lungs, is prevented by a very remarkable property of all animal membranes, skin, cellular tissue, muscular fibre, &c.,—namely, by their incapability of being permeated by concentrated saline solutions. It

is only when these solutions are diluted to a certain degree with water that they are absorbed by animal tissues. A dry bladder remains more or less dry in saturated solutions of common salt, nitre, ferro-cyanuret of potassium, sulpho-cyanuret of potassium, sulphate of magnesia, chloride of potassium, and sulphate of soda. These solutions run off its surface in the same manner as water runs from a plate of glass besmeared with tallow. Fresh flesh, over which salt has been strewed, is found, after 24 hours, swimming in brine, although not a drop of water has been added. The water has been yielded by the muscular fibre itself, and having dissolved the salt in immediate contact with it, and thereby lost the power of penetrating animal substances, it has on this account separated from the flesh. The water still retained by the flesh contains a proportionally small quantity of salt having that degree of dilution at which a saline fluid is capable of penetrating animal substances. This property of animal tissues is taken advantage of in domestic economy for the purpose of removing so much water from meat that a sufficient quantity is not left to enable it to enter into putrefaction. In respect of this physical property of animal tissues, alcohol resembles the inorganic salts. It is incapable of moistening, that is, of penetrating, animal tissues, and possesses such an affinity for water as to extract it from moist substances.

"When a solution of a salt, in a certain degree of dilution, is introduced into the stomach, it is absorbed; but a concentrated saline solution, in place of being itself absorbed, extracts water from the organ, and a violent thirst ensues. Some interchange of water and salt takes place in the stomach; the coats of this viscus yield water to the solution, a part of which, having previously become sufficiently diluted, is, on the other hand, absorbed. But the greater part of the concentrated solution of salt remains unabsorbed, and is not removed by the urinary passages; it consequently enters the intestines and intestinal canal, where it causes a dilution of the solid substances deposited there, and thus acts as a purgative. Each of the salts just mentioned possesses this purgative action, which depends on a physical property shared by all of them; but, besides this, they exercise a medicinal action, because every part of the organism with which they come in contact absorbs a certain quantity of them. The composition of the salts has nothing to do with their purgative action; it is quite a matter of indifference as far as the mere production of this action is concerned (not as to its intensity), whether the base be potash or soda, or in many cases lime and magnesia, and whether the acid be phosphoric, sulphuric, nitric, or hydrochloric. If we drink, fasting, a glass of common spring water every ten minutes, a strong diuretic action becomes apparent, the quantity of salts in the water being much less than that in the blood. When the second glass is taken, a quantity of urine is eliminated, the weight and volume of which corresponds nearly to that of the first glass; and by drinking twenty successive glasses of water, nineteen evacuations of urine take place, the last of which is colourless, and scarcely differs in its amount of saline ingredients from the spring water itself. When the same experiment is made with a water containing exactly the amount of salts as in blood ($\frac{3}{4}$ to 1 per cent. of common salt for example), a separation of urine is not effected, and it becomes almost impossible to drink more than three glasses of such water. A sensation of fulness in the stomach, of pressure and weight, seem to show that water containing an equal amount of saline ingredients as blood, requires a much longer time to be taken up by the blood-vessels. When the water taken contains a larger amount of salts than that existing in blood, a more or less active purgative action ensues. Hence, we see that three kinds of action take place, according to the quantities of salt existing in the water.

"Besides these salts, the action of which does not depend upon their power of entering into combination with the component parts of the organism, there is a large class of others which, when introduced into the living body, effect changes of a very different kind, and produce diseases or death, according to the nature of these changes, without effecting a visible lesion of any organs. These are the true inorganic poisons, the action of which depends upon their power of forming permanent compounds with the substance of the membranes and muscular fibre. Salts of lead, iron, bismuth, copper, and mercury belong to this class. When solutions of these salts are treated with a sufficient quantity of albumen, milk, muscular fibre, and animal membranes, they enter into combination with those substances, and lose their own solubility; while the water in which they were dissolved loses all the salt which it contained. The salts of alkaline bases extract water from animal substances; whilst the salts of the heavy metallic oxides are, on the contrary, extracted from the water, for they enter into combination with the animal matters. Now, when these substances are administered to an animal, they lose their solubility by entering into combination with the membranes, cellular tissue, and muscular fibre; but in very few cases can they reach the blood. According to all the experiments yet made on the subject, it appears, that after the lapse of the same time as is required for the appearance of alkaline salts in the urine, the metallic salts above mentioned cannot be detected in that fluid. In fact, during their passage through the organism, they come into contact with many substances by which they are retained. By degrees, however, the constituents of the tissues with which they have combined are altered by

the change of matter; their nitrogen appears in the urine, and along with it the mineral elements previously combined with the organic matter, such as mercury, copper, &c. When such substances enter into combination with organised parts, the functions of those parts must be disturbed, and must take an abnormal direction, producing morbid phenomena. The action of corrosive sublimate and arsenious acid is very remarkable in this respect. It is known that these substances possess, in an eminent degree, the property of entering into combination with all parts of animal and vegetable bodies, rendering them at the same time insusceptible of decay or putrefaction; it is further known that the parts of a body which come in contact with these substances during poisoning, and which therefore enter into combination with them, do not afterwards putrefy; so that there can be no doubt regarding the cause of their poisonous qualities. It is obvious that if they are not prevented by the vital principle from entering into combination with the component parts of the body, and consequently from rendering them incapable of decay and putrefaction, they must deprive the organs of the principal property which appertains to their vital condition, viz., that of suffering and effecting transformations; or, in other words, organic life must be destroyed. If the poisoning is merely superficial, and the quantity of the poison so small that only individual parts of the body capable of being regenerated have entered into combination with it, then eschars are produced—a phenomenon of a secondary kind—the compounds of the dead tissues with the poison being thrown off by the healthy parts." [Liebig's Chemistry of Agriculture and Physiology.]

Many salts are constituents of soils and of manures, and play an essential and highly important part in the nutrition of plants. Some are the sole ingredients in special manures; some are invariable and mighty ingredients in organic manures; not a few occur or are formed in all fertile soils; and many, either in themselves, or in their bases, or acids, or elements, or recombinations, contribute the whole or very nearly the whole of the inorganic principles or incombustible parts both of wild plants and of cultivated crops. Some, such as the carbonate of ammonia, the carbonate of lime, the sulphate of lime, the nitrate of soda, the nitrate of potash, the phosphate of lime, and the phosphate of magnesia, perform offices within the soil and in vegetation which constitute the main difference between barrenness and activity; and some, such as several of those just named and also the silicate of potash, the carbonate of potash, the carbonate of soda, the carbonate of magnesia, the oxalate of potash, the oxalate of lime, the malate of potash, the malate of lime, and many more are essential constituents of many of the most valuable or best known plants of either the garden, the field, or the wilderness. The carbonate of lime, for example, occurs in pease, vetches, wheat, barley, timber trees, and many other plants; the carbonate of magnesia is often associated in plants with the carbonate of lime; the sulphate of lime occurs in small quantities in clover, lucern, sainfoin, turnips, and potatoes; the nitrate of soda occurs in barley; the nitrate of potash, in woad, horse-radish, sunflower, and common nettle; the phosphates, in the seeds of the cereal grasses and of the sarcolobous legumes; the silicate of potash, in the culms of grasses; the carbonate of potash, in potatoes and in many shrubs and timber trees; the carbonate of soda, in fuci, salsolas, and most land-plants which grow near the sea; the oxalate of potash, in sorrel and some fuci; the oxalate of lime, in rhubarb, parsley, spinach, squills, fennel, and tormentil; the malate of potash, in rue, madder, nasturtium, lilac, and garden purslane; and the malate of lime, in wake-robin, houseleek, and mignionette. Some salts, also, occur in the roots, some in the stem, some in the leaves, and some in the seeds of the same plant; and several or even many sometimes occur, in a common association, either throughout an entire plant or throughout some of its parts. For example, no fewer than fifteen salts, besides some binary salt-like bodies, have been found in two of the most common fuci of the British shores,—the sulphate of potash, the oxalate of potash, the silicate of potash, the hydriodate of potash, the malate of potash, the muriate of potash, the carbonate of potash, the sulphate of soda, the carbonate of soda, the muriate of soda, the sulphate of magnesia, the muriate of magnesia, the phosphate of magnesia, the oxalate of lime, and the phosphate of lime. The multiplicity and importance of the range of saline action in the way of supplying direct nutriment to vegetables may be sufficiently inferred from our articles MANURE and FOOD OF PLANTS; the width and power and diversity of that action, in the way of preparatory or digestive transmutation of substances for the service of vegetation, may be partly conjectured from our articles MANURE, ALKALIES, LIME, AMMONIA, and NITRATES; and the particular action or actions of some of the most important salts, or of their constituent principles, either directly or indirectly or by recombination, may be learned from our articles MANURE, ALKALIES, ALUMINA, ACIDS, SODA, POTASH, LIME, CHALK, GYPSUM, AMMONIA, MAGNESIA, CARBONATES, NITRATES, PHOSPHATES, SILICA, and ASHES.

Many salts perform the whole of their fertilizing action, and others perform a main or considerable part of it, by undergoing decomposition, and letting loose their bases and their acids, to work out results independently of each other, and according to their respective nature; and in not a few instances, they set up a reciprocating process between decompositions and recombinations within the soil and decompositions

and recombinations within the vegetable organisms, which goes round a large circle or lengthens out to a prolonged series of feeding and vegetating effects. A large quantity of the alkalies and the alkaline earths is united in plants with a great variety of acids which are formed by the vegetable organisms, and which can be found nowhere but in vegetable juices and secretions; and all these alkalies, except perhaps in the few cases in which the vegetable salts may be supposed to spring direct from green manures or from the remains of dead plants or of dead parts of plants, must be derived from such a decomposition of mineral salts within the soil as drives the bases and the acids asunder, and allows the former to pass into the plants and the latter to remain entirely in the ground. The liberated alkalies and alkaline earths of the strongest or most characteristic mineral salts, such as the sulphates, the muriates, the nitrates, and the carbonates, in many instances, form new salts, of slender affinities or of plant-feeding elements, such particularly as the humates, before entering the plants,—and so carry up to the organisms, not only their own substance for combination with the vegetable acids, but also some elements to be pushed asunder from that substance, and appropriated to other departments of nutrition; and the acids of the decomposed mineral salts, when let loose on the soil, act on its most refractory constituents, such as its silica and its alumina, and form new mineral salts which, in their turn, play a similar part to that of the original salts. All the bases are thus digesting and carrying up the principles of the organic remains within the soil; all the mineral acids are attacking and reducing the constituents of gravel and slate and sandstone and metamorphic rocks and basalts within the soil; new supplies of bases are thus obtained, new absorbable preparations of organic remains are made, new evolutions of reducing acids are effected; and a continual circle of fertilizing process is thus going round. The action of mineral salts, in the way of manure, hence appears at once clear, mighty, and manifold; and can readily be understood to arise from very small doses; and, in all cases in which the requisite amount of basal and of organic matter exists in the soil, may easily be seen to be both certain and permanent.

Salts viewed as agents in vegetation, however, owe all their peculiarity of action to their acids; and, in order that they may be duly understood, they must be distributed into two classes, the one with organic acids, and the other with inorganic acids. "Perhaps no principle in agriculture," says Dr. Dana, "is better established than that an excess of any salt, in the usual acceptation of that term, is a cause of barrenness. Yet it is quite as well established, that the quantity of different salts admits of some latitude, and that some salts do produce better results than others. Referring to the acid constituents of these salts, it will be found that some acids are organic; they consist of hydrogen, carbon, oxygen, all which under the influence of the living plant, may be dissociated, and their elements form geine. Other acids consist of oxygen and nitrogen, essential constituents of plants; others consist of chlorine; others of sulphur and oxygen, and others of carbon and oxygen. In other words, the acids are composed of elements, which form food for plants, or of elements which enter in a small proportion only into the composition of plants. In the first case, the salts admit of a larger quantity being applied, than in the second. By the first, plants are fed,—by the second, they are poisoned; for the base of all salts acting, as has been explained, the acid is eliminated. If this is set free in large quantities, and its elements can be taken up and converted by the plant, well, good effects follow; if on the other hand, the elements of the acid are such as the plant demands not, its presence acts on the plant like poison on the animal economy. Let salts be divided into two classes, on this principle of the peculiarity of action depending upon the acid of the salts,—the first nourishes, the second poisons plants. The first class contains, first, carbonates—second, nitrates—third, phosphates.

"The action of the first class is to be studied under its three divisions. First, the carbonates. These include a very large portion of all salts used in agriculture,—such as limestone, marble, old mortar, shells, and shell marl. In all these cases, the base or lime, let loose by the action of the living plant, acts at once as caustic lime upon insoluble geine and unconverted vegetable fibre, changing these into soluble vegetable food; while the carbonic acid acts immediately upon silicates, decomposing these, and upon the geates in the soil, converting these into super-geates. Carbonates of alkalies, as ashes, &c., act at once; they are soluble, their alkali acts immediately upon the geine; their carbonic acid acts upon silicates and geine. Immediate and decided good effects follow their application; while carbonate of lime acts slower. All fat acids or fats and oils, also act upon silicates, partly by their own acid properties and partly by the evolution of carbonate acid gas, which is evolved during their conversion into the acid state. The quantity of carbonate of lime which may be applied is unlimited, and the quantity of alkali depends on the presence of insoluble geine. The more abundant is the last, the more freely may alkalies be applied. The carbonates include ashes of all kinds, and agriculturally viewed, all kinds of lime, for the quick soon becomes mild. The value of ashes in agriculture, depends upon their being a combination of salts, derived from plants, all of which have a powerful and decidedly beneficial effect. Peat ashes abound in carbonate, sulphate, and especially phosphate of lime. Free alkali may be always traced in peat ashes; but

alkali exists in it, rather as silicate, as in leached ashes. Anthracite coal ashes contain carbonate of lime, alumina, and oxide of iron; and it is good, so far as these abound.

"The nitrates, or second class of nourishing salts, include not only saltpetre, both East Indian and South American, or nitrate of potash and nitrate of soda, but also all composts of lime, alkali, and animal matter. These produce ammonia, which, without the lime would act on geine, and render that soluble. Ammonia, by the mere act of presence, hastens decay; but without the influence of lime, ammonia is changed to a nitrate of that base, or to nitrate of ammonia. Thus in a compost of animal matter without alkaline bases, not only has not all the geine been rendered as soluble, as is usually supposed, by the action of ammonia, but the absence of alkali has caused the ammonia, before its full action has occurred on the organic matter, to be converted into a nitrate of that base. But if the lime exceeds that which the nitric acid can saturate, then the soluble geine is seized upon, and becomes inert. Nitrates act under the influence of the growing plant, the base let loose acts on geine, the acid is decomposed, and nitrogen given up to the plant, and it becomes one of their essential elements. The elements of nitrate of ammonia are all taken up, both acid and base. If there are any salts which can be called vegetable food, they are the nitrates. The immediate effects of saltpetre or of any other alkaline nitrate are due to the liberated alkali, acting on the geine; and its permament effects, for experience has proved permanency of effect peculiarly due to nitrates, are owing to the liberation of an immense dose of oxygen, which is produced from the gradual decomposition of the acid. Now the insoluble geine condenses this in its pores, like charcoal. This condensation, like that of gas by charcoal, produces heat; it is like fermenting manure, while the condensed oxygen acts slowly on the geine, forming carbonic acid. It has upon the geine, buried in the soil, the same effect that tillage would have, rendering it soluble, with this additional advantage,—that its carbonic acid instead of escaping acts on the silicates. New portions of alkali are thus liberated, supplying for years that which was first applied, as a part of the saltpetre. The nitrates then, hold the very first place among salts, in agriculture.

"The phosphates—or third class of nourishing salts—include bones, horn, hair, nails, hoofs, and claws, and a large portion of the salts found in the liquid excretions of animals. These act much like nitre, the acid forming a constituent of the plants. It is not probable that the acid in this class is decomposed. It has not yet been proved that carbonates and nitrates exist already formed except in a very few plants. The quantity of salts which may be applied, will be greatest in the carbonates, next in the nitrates, and thirdly in the phosphates. The quantity of any salt which may be used will, after the largest amount, which can be safely employed has been ascertained, depend upon the farmer's ability to produce it. Carbonate of lime may be used to any extent, according to the farmer's idea of its value. Carbonates of alkali may be used with benefit. The largest quantity which has been known to be used without injury, has been 53 bushels of ashes per acre, which are equal to 240 lbs. of potash. The quantities used must be determined by experiment, and perhaps when the largest amount, which has been stated, is taken for a new starting point, the ultimate quantity will be found limited only by the geine in the soil, or applied in conjunction with the salt.

"If we now turn to the other division of salts, the poisons, that is those whose acid forms but a small portion of the elements of plants, we find two classes,—first, sulphates, as gypsum, copperas, Glauber's salt, all of which in small quantities are beneficial. An explanation, which attributes the action of sulphate of lime or plaster, to its power of decomposing and fixing in soil carbonate of ammonia ought to show, first, the actual presence of that salt in air,—second, that sulphate of ammonia is not decomposed by the resulting carbonate of lime in the cold,—and third, that common salt would, in equivalent quantity with plaster, produce equally good effects. It never has, and therefore this explanation is not correct.—Secondly, muriates or chlorides, as they are strictly called, as common salt, muriate of lime, bittern, spent ley from soap-works. Common salt has been found beneficial when applied at the rate of 30 bushels per acre; and at 14 bushels per acre, was found to produce effect next best to 53 bushels of ashes per acre; but quick lime at 26 bushels per acre on the same land, produced no good result.

"In all this action of salts, it is seen that the presence of life seems almost essential. Whatever the vital principle be, it may be best represented as analogous to electricity and galvanism. In this point of view, the salts present themselves in a new relation,—in a relation, in which alone, they may be said to be stimulants or excitants. Plants and soil act, it may be supposed, for illustration, by forming galvanic batteries or piles with each other. The most active element in the pile is the growing plant. It is an acknowledged fact, that chemical action, if not the source is ever attended by electrical effects. An acid, in contact with an alkali, or metal, always produces chemical action; but the silicates of the soil are already combinations of acid and metals; hence as such, they have no tendency to act on each other. If there be added to these a salt or an acid, chemical action, decomposition begins. The electricity is, we may say, excited by salts—they are in this sense, and in no other, excitants or stimulants. The very first act of vegetation, the germination of seeds,

induces this electric action, this decomposition of the elements of soil. Germination produces carbonic acid, by decomposing water. The very first act of life in a seed is to evolve carbonic acid, by its carbon combining with oxygen of air, and its second act is to decompose water. Its oxygen combines with the carbon of the seed; a single bean produces many times its bulk of carbonic acid gas; and in the soil would surround itself with an atmosphere of carbonic acid. This evolved, begins its action upon the silicates. The living seed begins the electric action, and the plants exert and keep up this influence. Salts act in a similar way; but above all, over all, influencing all, is the living plant. This electric action induced, extends to undetermined distances; hence there is a transfer, as is usual in all cases of galvanic decomposition, of substances remote from the plant, to its root, where they are taken up. It is not the potash and lime, &c., immediately in contact with the root, which alone supplies the plant; but under the galvanic influence, an undetermined portion of soil is decomposed. This decomposing agency of plants wholly destroys all confidence in experiments, undertaken to prove that pure water alone can nourish plants. The containing vessel, that is the vessel in which the experiment is made, is itself always decomposed. If to guard against an error glass is used, it has already been shown that this is only a combination of silicates, and these will be transferred from the glass to the plant."

SALT (Common),—chemically *Chloride of Sodium.* A compound of one equivalent of chlorine and two equivalents of sodium. It may be directly formed by burning sodium in chlorine, or by heating it in hydrochloric acid gas; and it is deposited in crystals from a solution of muriate of soda. But it naturally occurs in vast quantities as a mineral deposit of the saliferous sandstone formation,—in immense quantities as a saline impregnation of sea-water and of the water of salt springs,—and in small quantities as a sapid ingredient of most of the waters which flow from any part of the land into the sea. It may be regarded as a true mineral; for it is always the solid or ultimate form into which the muriate of soda of the sea and of salt springs is resolved by evaporation; and it passes from the interior of all countries toward the final receptacle of rivers; and it generally accumulates more, and forms a stronger brine, in inland seas which have no outlet, and particularly in such a narrow evaporating basin as the Dead Sea, than in the open and far-expanding ocean. Its crystals, from slow evaporation, are cubic,—and from rapid evaporation, are hollow, four-sided prisms; and they contain no water of crystallization, but enclose particles of water among their interstices, and decrepitate powerfully when heated. Its taste is agreeably saline. It slightly deliquesces in a moist atmosphere, but undergoes no change in a dry one. It fuses at a red heat, and cools down into a brittle transparent mass. It dissolves in about $2\frac{1}{2}$ times its weight of water, of any temperature from 60° to 212°; and it passes into muriate of soda in the act of dissolving. Solid common salt is thus akin in constitution to an oxide, and consists of two simple or elementary ingredients,—a metal and a salt radical; and dissolved common salt is strictly a true salt, and consists of two compound or binary ingredients,—an oxide and an acid.

The Varieties of Salt.—The ordinary common salt of the useful arts, in all its varieties of fishery salt, bay salt, and stored salt, is obtained by evaporation of sea-water; and is very seldom pure, or even nearly pure; and often contains a considerable intermixture of the other salts which are associated with muriate of soda in the sea. See the article Sea-Water. The sulphate of magnesia, the muriate of magnesia, and the sulphate of lime which occur in it may be precipitated as carbonates, by boiling a solution of it during a few minutes with a slight excess of carbonate of soda, and then filtering the liquid, and neutralizing it with muriatic acid. The differences which exist among the many varieties, arise solely from diversities in the mode of preparation; and the chief groups of the varieties are common British salt, foreign bay salt, and Dutch salt. A specimen of common Scotch salt analysed by Dr. Henry contained 0·4 per cent. of insoluble matter, 2·8 of muriate of magnesia, 1·5 of sulphate of lime, 1·75 of sulphate of magnesia, and 93·55 of chloride of sodium; a specimen of Sunday Scotch salt contained 0·1 per cent. of insoluble matter, 1·15 of muriate of magnesia, 1·2 of sulphate of lime, 0·45 of sulphate of magnesia, and 97·1 of chloride of sodium; a specimen of common Lymington salt contained 0·2 per cent. of insoluble matter, 1·1 of muriate of magnesia, 1·5 of sulphate of lime, 3·5 of sulphate of magnesia, and 93·7 of chloride of sodium; a specimen of cat Lymington salt contained 0·1 per cent. of insoluble matter, a large trace of muriate of lime, 0·5 of muriate of magnesia, 0·1 of sulphate of lime, 0·5 of sulphate of magnesia, and 98·8 of chloride of sodium; a specimen of St. Ube's bay salt contained 0·9 per cent. of insoluble matter, a trace of muriate of lime, 0·3 of muriate of magnesia, 2·35 of sulphate of lime, 0·45 of sulphate of magnesia, and 96·0 of chloride of sodium; a specimen of St. Martin's bay salt contained 1·2 per cent. of insoluble matter, a trace of muriate of lime, 0·35 of muriate of magnesia, 1·9 of sulphate of lime, 0·6 of sulphate of magnesia, and 95·95 of chloride of sodium; a specimen of Oleron bay salt contained 1·0 per cent. of insoluble matter, a trace of muriate of line, 0·2 of muriate of magnesia, 1·95 of sulphate of lime, 0·45 of sulphate of magnesia, and 96·425 of chloride of sodium; a specimen of Dutch salt, in large and very small crystals, analysed by Professor Traill, contained 0·065 per cent. of insolu-

ble matter, 0·044 of muriate of lime, 0·506 of muriate of magnesia, 0·7 of sulphate of lime, 0·398 of sulphate of magnesia, and 98·287 of chloride of sodium; a specimen of Dutch salt, in smaller grain than the preceding, but still remarkable for the regularity of its crystals, contained 0·09 per cent. of insoluble matter, 0·099 of muriate of lime, 0·201 of muriate of magnesia, 0·4 of sulphate of lime, 0·2985 of sulphate of magnesia, and 98·9115 of chloride of sodium; and a specimen of Dutch salt, in less regular and much smaller crystals than the preceding, but still more symmetrical in crystal than British salt of the same size of grain, contained 0·07 per cent. of insoluble matter, 0·0935 of muriate of lime, 0·1765 of muriate of magnesia, 0·57 of sulphate of lime, 0·4415 of sulphate of magnesia, and 98·6485 of chloride of sodium. The analysis of specimens of four different kinds of Cheshire rock-salt may be advantageously compared with these analyses of sea-salts, for the purpose of guiding purchasers who use large quantities of salt as a condiment for cattle, and especially as an antiseptic. A specimen of crushed rock-salt, analysed by Dr. Henry, contained 0·1 per cent. of insoluble matter, 0·0063 of muriate of lime, 0·0187 of muriate of magnesia, 0·65 of sulphate of lime, and 98·325 of chloride of sodium; a specimen of fishery rock-salt contained 0·1 per cent. of insoluble matter, 0·025 of muriate of lime, 0·075 of muriate of magnesia, 1·125 of sulphate of lime, and 98·675 of chloride of sodium; a specimen of common rock-salt contained 0·1 per cent. of insoluble matter, 0·025 of muriate of lime, 0·075 of muriate of magnesia, 1·45 of sulphate of lime, and 98·35 of chloride of sodium; and a specimen of store rock salt contained 0·1 per cent. of insoluble matter, 0·025 of muriate of lime, 0·075 of muriate of magnesia, 1·55 of sulphate of lime, and 98·25 of chloride of sodium.

"On comparing these analyses," remarks Professor Traill, "we find that the Dutch salt is very superior in purity to bay salt, and still more so to most of the salt obtained in Britain from sea-water. The specimens even surpass in purity the salt prepared from Cheshire rock-salt. This is chiefly owing to their containing less sulphate of lime than the salt of Cheshire; while, however, they are contaminated with larger proportions of the earthy muriates and sulphate of magnesia, from all which the Cheshire salt is remarkably free. The contaminating saline ingredients which are most detrimental to salt, as a preservative for meat, are undoubtedly the earthy muriates or hydrochlorates, and next to these, the sulphate of magnesia, because they are either very soluble or deliquescent, and therefore cause rapid melting of the common salt, into which they largely enter, and thus its value in the preservation of fish and flesh is greatly impaired. When a salt of easy solubility is applied to preserve fish or flesh, it soon dissolves in the animal juices, and readily absorbs moisture from the air; in that case, the upper portions of the fish or flesh are speedily deprived of the salt, and thus become liable to pass to putrefaction. The remarkable purity of the Cheshire salt from deliquescent saline contaminations, would seem to point out its peculiar fitness for the fisheries, and the salting of animal flesh; yet I believe it is admitted, that Dutch salt is preferable for the first, which must depend on some of its other qualities. On examination, it would seem that its value for such purposes depends on its superior hardness, and the size of its grain. The large-grained and dense salt, when strewed between the layers of fish or flesh in a cask, every other thing being equal, will remain longest solid, and by its very gradual dissolving, continue to afford a succession of saline particles to the upper portions of the animal matter, as well as to the lower, and to keep it thoroughly impregnated with salt. A large-grained hard salt has been formed by a slow evaporation; and if the very pure salt of Cheshire were crystallized more slowly than it is, there can be no doubt that it would afford a fishery salt superior to every other now in use. For the first part of the process of salting meat, the formation of the brine for immersion of the animal matter, and what is called striking it with salt, the small-grained pure salts are perfectly applicable; and for this purpose, I do not think that the third kind, or even the second kind, of the Dutch salt, mentioned in the analysis, has any superiority over the Cheshire salt; but the large and hard grain of the first kind of the Dutch salt more than compensates for any little inferior degree of purity, when employed for strewing between layers of fish or flesh in the casks. For the due preservation of butter, no kind of salt seems preferable to the larger grained varieties of Cheshire salt. The sulphate of lime, as it exists in this salt, is of small consequence; while its extreme purity from the contamination of earthy hydrochlorates and of the bitter sulphate of magnesia, render it but little likely to impart any disagreeable flavour to that delicate article of diet."

Rock salt occurs in the sides and bottoms of salt lakes in America, and in vast beds of the saliferous sandstone formation in England, in Continental Europe, and in most other parts of the world. The beds of it in Cheshire vary in thickness from 4 to 130 feet; and alternate with limestone, clay, swinestone, sandstone, and indurated, gypseous marls. It occurs both massive and dentiform, and also in straight and curved fibrous concretions, and is commonly yellowish, greyish, or very white, with flesh-coloured, red, and violet stripes, and is highly translucent or almost semitransparent, and breaks into splintery fragments, and presents externally a resinous lustre, and internally a shining and glistening appearance; and, when exposed to strong heat either on the coals or from the blow-pipe, it smartly decrepitates. A peculiar kind of it decrepitates

in water, and, in the process of dissolving, emits a gas of similar composition to carburetted hydrogen. The coloured varieties owe their colour to the presence of animalcules; and even the clear kind, as well as the red, contains a monad, which may readily be seen by placing a few particles of the salt with a little water on the object-glass of a microscope, and observing the residue after the salt is melted.

The Uses of Salt in the Arts.—Salt is the most commonly used of all antiseptics for the preserving of meat. See the section "Salting of Meat" in the article MEAT. It is also employed in large quantity for the manufacture of bleaching-powder, hydrochloric acid, and the best carbonate of soda. "In preparing hydrochloric acid from salt, which is done by the aid of the oil of vitriol, sulphate of soda is formed, from which, by heating it with charcoal, carbonate of soda is obtained. Thus, in the very important manufacture of soda from salt, both the chlorine and the sodium are made use of, the hydrochloric acid being but a secondary product, formed in the first stage of the manufacture of carbonate of soda, a product nearly equal in importance to the oil of vitriol, by means of which it is made."

The Uses of Salt to Animals.—Salt, in small quantities, and in accompaniment with food, is highly relished by man and by almost all quadrupeds, whether domesticated or wild; and acts at once as a condiment, for giving agreeable sapidity to food,—as a tonic, for assisting the process of digestion,—as an aliment, for contributing certain principles to the blood and some of the liquid secretions,—and as a medicine, both to prevent some diseases in a healthy system, and to aid or effect the cure of others in a morbid one. It renders many articles of food grateful, both raw and prepared ones, which would otherwise be nauseous; it produces a heat, a stimulation, and a gentle causticity in the stomach and the small intestines, which always assist digestion, and are often essential to it; it contributes the free hydrochloric acid of the gastric juice, the soda of the bile and the blood, and the soda salts of some other animal fluids; and it prevents worms in man and rot in sheep, and putrefactive tendencies in all animals who use it, and operates as an useful aperient and a mild restorative under various forms of both acute and chronic disease. The efficacy of it against parasitical worms in man will sufficiently illustrate its general value. "A lady is spoken of in the London Medical Journal who had a natural antipathy to salt, and was consequently most dreadfully infested with worms during the whole of her life. In Ireland, where, from the bad quality of the food, the lower classes are greatly infested with them, a draught of salt and water is a popular and efficacious cure. Dr. Paris has noticed the bad effects of a diet of unsalted fish. Rush says that he has administered many pounds of common salt with great success in worm cases. Lord Somerville, in his address to the Board of Agriculture, gave an interesting account of the effects of a punishment which formerly existed in Holland. 'The ancient laws of that country ordained criminals to be kept on bread alone, unmixed with salt, as the severest punishment that could be inflicted upon them in their moist climate. The effect was horrible; these wretched criminals are said to have been devoured by worms engendered in their own stomachs.' The wholesomeness and digestibility of our bread are undoubtedly much promoted by the addition of salt which it so universally receives. Dr. Dyer says, that in the Mauritius, the planters' slaves rarely obtain salt, and are therefore extremely subject to worms, while the government slaves and the convicts get salt in their rations, and seldom suffer from those intestinal parasites. Some planters, regarding economy and the health of their slaves at the same time, give a table-spoonful of salt in half a pint of water to each slave regularly every Saturday after work; and they find that this dose acts not only as a vermifuge, but as a tonic."

The uses of salt, whether condimentally or medicinally, for all kinds of live stock, are quite as extensive and varied as the uses of it for man, and in many respects are the same, but in others are different. It gives sapidity and relish to grasses, hay, and other kinds of raw food; it acts universally as a stimulus to digestion; it renders coarse food more nourishing, and moist food less injurious; it restores the tone of the stomach when impaired by excess of either food or labour, and often recals the appetite more speedily than any other tonic; it preserves health, and improves the general condition; it is a purgative second only to Epsom salt when given in the first instance, and acts with high certainty when preceded by a dose of Epsom salt which fails to purge, but, in consequence of its being a tonic as well as an aperient, it is unsuitable in an early stage of any fever; it acts with great power and general efficiency as a vermifuge; it serves, in external application, as an excellent discutient, a hardener of sore places, and an abater of inflammation; it improves the quality of excrement for the purposes of manure; and it so greatly tames the disposition, and overcomes natural timidity, that sheep gather round a shepherd to receive distributions of it, and the wildest cattle come to lick it out of the hand. In all its internal uses, however, whether as a condiment or as a medicine, it requires to be administered in small and measured quantity; for whenever it is given too freely, it not only does no good, but may produce very serious evil.

Salt is of great use to horses. It makes them relish their food, and incites them to work well, and assists their general health and condition, and is a preventive or a cure of bots and grease. A quantity of about four ounces in the day, sprinkled in several doses of about a table-spoonful each

on their steamed potatoes or on their other crib food, is peculiarly appropriate. A poor torn-down horse, if put into a salt-marsh, may, by means of the salt which he there receives with his food, be purged and cleared of every disorder, and speedily become fat. The horses of many parts of America are daily fed each on from 4 to 5 gallons of oats, besides hay, and receive each a good handful of salt about twice a-week; and they are excellent workers, and continue in high condition, even when performing long journeys at the rate of 45 miles a-day. Some horses in whose manger a lump of rock salt has been regularly laid every spring and autumn, have eagerly licked it, and have, with little exception, continued in good health during 14 years. Horses about to be called out to extraordinary exertion have received a little salt by way of preparation for their work, and seem to have been sustained by it under their extreme fatigue in a similar way to the camels who receive a little salt during the passage of the caravans across the deserts of the East.

Salt has the same effects on the ass and on the mule as on the horse. Wild asses feed chiefly on the most saline and bitter plants of the desert, such as the salsolas, the atriplices, and the chenopodiums; and they seem to recognise and relish saline vapours at a comparatively great distance from the sea or from lakes, and in consequence readily discover distant waters by the smell. The mules who work in the Real del Monte silver mines in Mexico have such a greed for salt that they constantly lick the ore, which consists of mercury and sulphuret of silver in amassment with salt and with iron pyrites; and, though they in consequence take in large impregnations of the metals, they suffer no inconvenience; and, on opening them after death, considerable quantities of silver are sometimes found amassed in their stomach.

Salt has been known from ancient times and in mutually far-distant countries to be highly beneficial to cattle. Pliny, in his Natural History, tells us that cattle have an avidity for salt pasture, and that cows who graze on it give milk in larger quantity and of better cheese-making quality than cows fed on insaline lands. Dickson, in his Husbandry of the Ancients, says that the Romans prepared the straw for cattle-food by steeping it for a considerable time in brine, and then drying it, and rolling it up in bundles. An American writer in the Museum Rusticum, about 85 years ago, said, "We think salt in a manner absolutely necessary, and accordingly give it to every kind of cattle; and to this practice of feeding with salt, it is generally ascribed that our cattle are so much more healthy than the same animals in England; certain it is that they are subject to much fewer diseases." In some parts of Africa, large herds of cattle travel from great distances, at stated seasons, to enjoy the marine plants which grow on the coast and are saturated with sea-salt. The fattening property of our own salt marshes is well known to graziers and farmers. In Smith's Wonders, it is stated that the water of the salt mines near Eperies, in Upper Hungary, affords a blackish salt, which is generally given to cattle. For many years, it has been the custom in Germany, and particularly in Wirtemberg, where a vast number of oxen are bred, to give doses of glauber salt to cattle. As long as common salt was more expensive than glauber salt, it was thought that the inhabitants of Wirtemberg used the latter through economy; but this supposition must have been erroneous, as they still continue to use glauber salt, although the discovery of salt springs has rendered the domestic salt exceedingly cheap. The reason they assign for this preference is, that it conduces, by its purgative qualities, to keep the cattle in good health, and that even when, from long habit, they become less liable to be acted on by it, it still promotes digestion, and brings the beasts into good condition more rapidly. Matthew Aphonin, a Russian naturalist, remarks that "oxen fatten very quickly upon the sea-coasts where the arrow-grass, *Triglochin maritimum*, their favourite food, abounds;" and if this be so, it is probably ascribable to the saline nature of the plant, and to the sea breezes containing particles of salt. In Upper Canada, the cattle have plenty of wild pasture to brouse on in the woods; but, once in a fortnight, they return, of their own accord, to the farms, to obtain a little salt; and when they have eaten it, mixed with their fodder, they repair again to the woods. D'Azara tells us that, in some parts of Paraguay, salt is not given to the herds of cattle; but they are supplied with the barrero, a saline or nitrous earth, which they and other animals seek with avidity, and without which they fail and die in the course of four months. From the 27° of south latitude to the Malovine Islands, they have no need of the barrero, because the water and pasture-grounds are sufficiently salt; but northward, beyond this latitude, it is necessary, and the plains which do not contain it, feed neither the ox, horse, ass, mule, goat, nor sheep. In India, salt is given to bullocks daily, to the amount of 2 or 3 ounces, in their feed of pulse, or of a mixture of grain, vetches, and chaff; and so efficacious is it with this mixture of food as, in six or seven months, to render bullocks of 16 years of age, who have become superannuated from active service, as fit for the shambles, or as fine in the quality of their beef as the majority of oxen seen in the annual shows of Smithfield. A small quantity of salt in accompaniment with clover, turnip-tops, and other green and succulent food, tends to prevent hoove.

Salt is sometimes very serviceable to fattening calves. When a sucking calf does not get enough of milk, and requires to be fed with oatmeal-gruel, he may sicken and die if the gruel be salt-

less, but will thrive if it be salted; and when a calf who is fed solely on milk becomes disordered in stomach, and loathes his food, and does not increase in fatness, he will acquire a fine appetite, and begin rapidly to fatten, by means of the simple expedient of giving him small doses of salt dissolved in water. An able experimentalist, who gave evidence on the subject before a Committee of the House of Commons, currently allowed each of his calves one ounce of salt per day, and each of his milk-cows four ounces, and each of his feeding oxen from four to six ounces.

Salt is highly advantageous in many ways, to sheep. It averts the injurious effects of moist and humid situations where they may be required to graze. It greatly diminishes the loss or risk of depasturing them on such wet retentive lands as otherwise constitute unsound and sickening pastures. It prevents rot, braxy, scab, flatulent distension, intestinal worms, and other diseases which they are liable to contract from either unfavourableness of situation, changeableness of climate, or succulency of food. It promotes their general health, and modifies their natural timidity, and brings them very closely and submissively under the shepherd's care; and, whether artificially given, or merely aspersed on pastures by the sea-spray, it considerably improves the natural wool. In Spain, it is given to the amount of 128 lb. a-year to every 1,000 sheep; but in many parts of Britain, it might be given with advantage to the amount of so much as a ton to every 1,000 sheep; and in all very bad situations, it ought to be supplied in as large a quantity as they choose to consume. It should be given in the morning, in order that it may counteract the effects of the dew; and it may be supplied in ordinary cases twice a-week, and in extraordinary ones thrice. Ten or fifteen slates or small flat stones for holding it may be placed at distances of a few yards from one another for every 100 sheep; and a small handful may be laid on each. If the sheep have a craving for it, they will quickly lick it up; and if it do not seem to be quite to their present taste, it should immediately be gathered up again, and reserved for future use. See the articles Rot and Braxy.

Salt, in moderate quantity, promotes the health and accelerates the fattening of hogs. It should be mixed with their food at the rate of a large table-spoonful in 24 hours; and may be advantageously given in larger quantity, in cases where they eat it greedily and are observably affected by it as a purgative. When the use of it was introduced to the Irish piggeries, hogs were found to fatten in little more than half the time which was formerly common, and were found also to acquire a greater bulk of eventual fat. Salt is sometimes given to the hogs of America to render them tame, and to prevent them from irretrievably wandering or becoming wild in the forest.

All the quadrupeds of North America, both domesticated and wild, native and imported, have an instinctive passion for salt; and the ox, the bison, the deer, the elk, the bear, and other large animals, however strong may be their natural antipathies, and however distant their pasture-grounds, repair periodically to the saline and briny springs which are interspersed all over that great continent; and, in some instances, they have abraded the briny bottoms and luxuriated in the saline waters and licked the salt rock, till great excavations of 8 or 10 feet in depth have eventually been made, and most fantastic shapes of surface have eventually been fashioned. The argali or wild sheep who inhabits all the alpine regions of Central Asia, and occurs on the highest mountains of Greece, Corsica, and Barbary, is very fond of salt, and sometimes excavates the earth to a considerable depth to obtain it. The Scythian antelope, who frequents the open and dreary deserts around Mount Caucasus, near the Caspian Sea, and in Siberia, feeds largely on salt and on the plants which grow near salt springs. The chamois, who occurs chiefly on the Alps and the Pyrenees, and who feeds on the most delicate herbage it can find, is very fond of salt. Gazelles, who live in immense herds in the open plains, browze upon the saline and pungent herbage. And camels drink water which is too salt to be used by their human masters.

The Uses of Salt in the Cultivation of the Soil.—Salt, even in small quantities, operates fatally on cold-blooded animals, both of the land and of fresh water; and is therefore a convenient agent for easily clearing away worms, molluscs, newts, various insects, and other small animal nuisances. The warty newt, though generally very tenacious of life, dies with the most violent convulsions under a little sprinkling of salt; and snails, slugs, earthworms, and some common insects are speedily killed by an aspersion or syringing of brine or other strongly saline liquid. A sprinkling of salt on lawns, at the rate of ten bushels per acre, prevents worm-casts; a good watering of gravel-walks and other parts of gardens with a strong solution of salt kills worms and grubs and larvæ, and greatly aids to keep the walks and grounds in good order; the application of a strong solution of salt to various plants and beds with a garden syringe destroys some noxious insects; and the mixing of salt with seed-corn, or the aspersion of it as a top-dressing, is one of the surest agricultural appliances, for protecting the young corn-crops of the farm from some of their worst subterrane assailants. "In some parts of Scotland," says Sir John Sinclair, "where the oat-crops were frequently destroyed by grubs, &c., it has long been a practice to mix salt with the seed, in the proportion of 1 to 32, but sometimes 1 in 16. Every means has been taken to ascertain the utility of the practice, and with uniform success. Salt destroys vermin in the

ground, by making them void the contents of their bodies, such evacuations being too powerful for them to withstand. It has this additional advantage, that the vermin thus become food for those very plants which otherwise they would have destroyed."

Salt, used in various ways, is a well-known preventive or remedy of the fungal diseases of the cereal crops. The application of it as a manure or top-dressing tends more or less to prevent both rust and mildew; yet cannot always be depended on, and requires the exercise of some caution. Manuring with the refuse salt from the pilchard fishery in the South of England, was long ago found to be a constant preventive of rust in a district where the disease infested all the unsalted lands. The cautious aspersion of a clean solution of salt is one of the best known cures for actual mildew. See the articles Rust and Mildew. The immersion of seed-wheat in a brine of sufficient strength to float an egg, followed by the frequent stirring of the steep and the skimming away of all the light and unsound grains which rise to the top, has long been practised throughout a great part of England as a preventive of smut. See the article Smut.

The value of salt, in small quantities, as a manure, appears to have been well known in ancient times. Cato, Virgil, Pliny, and Columello all record its power of improving the herbage of pastures or the dried fodder of cattle; and two remarkable sayings in the Gospels — that the apostles of the Redeemer were "the salt of the earth," and that salt which has lost its savour "is neither fit for the land nor yet for the dunghill"—seem to point to a prevailing practical acquaintance, throughout the civilized world or at least in Palestine, with the fertilizing properties of salt. The use of it on sheep pastures or with sheep feed has been observed in Spain from the earliest times, and became known at an early period in Germany; the efficacy of it against "murrain or rotte," was known in England in the 16th century; and the direct fertilizing powers of it upon the soil were tested by experiment at Clapham about the middle of the 17th century. But salt became lost to British agriculture, in the reign of William III., by the imposition on it of a war-tax which raised the price of it from 6d. to upwards of 20s. per bushel: and it did not become available till the repeal of the tax in 1823. Many farmers were now totally ignorant of its adaptation to manurial purposes; and others made experiments with it in methods so loose, inaccurate, and preposterous as either to defeat its success or to bring it under serious suspicion. Most farmers, therefore, continued long indifferent about it; and some hotly disputed or angrily denied its claim to rank as a manure; and only a few, by means of enlightened experiment and patient recommendation, eventually brought it into general favour.

Salt operates in various ways as a fertilizer; but must always be applied in small quantity, and with due adaptation to one or more or all of its specific modes of action; for if used in excess or at improper times or in unsuitable circumstances, it may be useless or even hurtful. It is a direct though scanty principle of the food of some plants; it affords other principles of the food of plants, particularly soda, in result of a short and easy process of decomposition and recombination; it converts many hurtful organic bodies and refractory organic matters in the soil into principles of nutrition; it assists the complex, ameliorating chemical processes of fallowing, in their action on both the minerals and the artificial manures of the soil; it stimulates the organisms and accelerates the secretions of growing plants; it mitigates the evils of sourness and coldness and wetness in moist, stiff, grass lands; it promotes the tenderness and sapidity of gramineous herbage; it promotes the vegetation of oily seeds; it assists the action and increases the power of lime and soot and other artificial mineral manures; and it renders the soil to which it is applied more absorbescent of moisture from the atmosphere, and helps to protect both it and the crops growing on it from the injurious effects of great and sudden vicissitudes of temperature.

As to most of the methods in which salt acts directly as a fertilizer, however, it naturally exists in quite sufficient quantity in all localities near the sea, and requires to be artificially applied only in places which are little visited with saline vapours. "If we examine into the results of the experiments which have been made with salt as a manure," says Dr. Madden, "we shall find that, after leaving out those where obvious mistakes in quantity were made, they directly corroborate the opinion that the applicability of a special manure should be determined by analysis, in order to prevent the probability of a failure; for it will be found, by examination, that, in those cases where it either produced no effect, or was injurious, the soil was in a situation to receive supplies of salt from natural sources; whereas, the situations where salt is useful as a manure, are such as to exclude these natural supplies. It may not be generally known that the clouds which form over the sea always contain a greater or less quantity of salt, which of course will be deposited in the soil by the rain; and, moreover, that during the occurrence of sea-breezes, the spray travels to a very considerable distance inland, and is likewise deposited on the land. From these two sources it may be premised with comparative certainty, that places near the sea, particularly such as lie in the direction of the prevailing sea-breezes, will obtain a sufficiency of salt, whereas inland situations will, in all probability, be much benefitted by an artificial supply. To give some idea of the quantity of salt contained in clouds near the sea, I may

state that I last year analyzed the rain which fell at Penicuik, and found it to contain so large a proportion of salt, that, calculating the fall of rain at 31 inches per annum, each acre would receive 641 lbs. or nearly 6 cwt. of salt from this source alone. From detailed accounts of various experiments with salt, made in different situations, and published in the Transactions of the Highland Society, we find, that on the farm of Forest near Stonehaven, Kincardineshire, a spot freely exposed to the frequent east winds coming directly from the German Ocean, salt either entirely failed, or acted very injuriously, and in no one experiment produced an encouraging result,—that at Barnyards in the county of Aberdeen, a place somewhat similarly situated, no effect whatever was produced by salt as a manure,—that at Mount Annan, Dumfries-shire, near the Solway Firth, where the south-west winds will bring the spray to shore, salt produced little or no effect upon wheat, turnips, or flax, but was found useful for pasture, on which it had nearly as much effect as shell-lime,—that at Almond Myrehead, near Linlithgow, where, whatever be the direction of the wind, it must sweep over several miles of land before it can reach this spot, salt was found beneficial in every instance where it was judiciously applied, giving an increase both in measure and weight of grain, and in potatoes producing 11¼ bolls more per acre. And, in the experiments with salt published in Professor Johnstone's 'Suggestions,' the most beneficial results were obtained in the neighbourhood of Glasgow and Paisley." Every farmer, then, who would judiciously use salt as a fertilizer, particularly in any direct application of it in the way of top-dressing or of ordinary manuring, ought to ascertain as exactly as possible the natural constitution of the soil to which he intends to apply it; and should withhold it altogether, or give partial or full doses of it, according as the land receives ample supplies of it, or limited ones, or scarcely any, from sea-vapours or other natural sources. Another and all-important precaution in the use of salt as a direct fertilizer, just like a nitrate or gypsum or lime or any other special manure, is not to rely on it alone for feeding and rearing a crop, but to see that all the other requisite principles of the crop's food be present in the soil. See the article SEA-WATER.

In using salt in aid of the fallow process, for destroying slugs and larvæ and other small vermin in the field, and for assisting to disintegrate hard clods, to pulverize adhesive ones, and to mellow the whole texture of the ground, it may be sown in autumn, some time before the land is ploughed, at the rate of from 30 to 40 bushels per acre. "The salt being thoroughly incorporated with the soil during the following spring and summer," says Sir John Sinclair, "the strength of it will be so much reduced, when the seed is sown, that instead of injuring it will promote vegetation; and the lands, it is said, will be found to produce a crop superior to those under any other mode of cultivation, the advantage of which will be experienced for several succeeding years."

Salt, in suitable circumstances of place, time, and quantity, acts well upon the cereal crops. R. Legrand, Esq., sowed it on a barley tilth, at the rate of 16 bushels per acre, immediately after the crop was covered by the harrow; and he found the verdure in spring greater, and the ripened appearance in autumn many degrees whiter, than he had ever before witnessed. Mr. Hollinshead recommends the sowing of 16 bushels of salt per acre on potatoes, as soon as they are covered with earth,—and maintains that, by this means, alternate crops of them and of wheat might be permanently produced on the same soil; and though this opinion is far too sanguine, and requires to be greatly qualified, yet, when viewed as coming from a man who made scientific and practical enquiry into the uses of salt during a period of upwards of twenty years, it must be received as a strong testimony, in a general way, to the beneficial action which this manure exerts on wheat. Cuthbert W. Johnson, Esq., made comparative trials of it, on a light and gravelly soil at Great Totham in Essex; and found the produce per acre on a part which received no manure at the time, and which had not been manured for four years, to be 13 bushels and 26 lbs.,—on a part which he manured with stable dung to a crop of potatoes on the preceding year, to be 26 bushels and 52 lbs.,—and on a part which he manured with 5 bushels of salt per acre, and which had received no other manure for four years, to be 26 bushels and 12 lbs.; and he recommends that salt for wheat be applied some time before sowing the seed, in a dose of not less than 10 and not more than 20 bushels per acre. Mr. Hannam made comparative trials of salt and other special manures upon oats, barley, and wheat; and arrived at the general conclusion respecting salt, that, in the case of oats, it has a tendency to increase both the quantity and the quality of the grain, and to increase the quantity of grain in a greater ratio than the quantity of straw,—that, in the case of barley, it has a tendency to increase the quantity of grain in a greater ratio than the straw, to improve the quality of the grain, and to render the straw white and brittle and to promote its ripening,—and that, in the case of wheat, it tends slightly to increase the produce of the grain, to increase the weight of it per bushel, and to decrease the weight without diminishing the bulk of the straw, and may therefore be advantageously used as an auxiliary to other manures. The quantity he used per acre was 24 stones; and the results he obtained, comparatively with those from nitrate of soda, nitrate of potash, guano, and rape-dust, were highly favourable. See the section "Special Manures" of the article MANURE. Mr.

George Sinclair, with his accustomed scientific accuracy, and in a variety of different ways, made some important experiments, at Woburn, on the use of salt, by itself and in compost and in different quantities, as a manure for Talavera wheat, employing plots of sandy soil each 36 feet square, drilling in the seed on the 5th of November, and reaping the crops on the 2d of August; and the following tabular report of his experiments, though not at all to be taken as an index of what may be expected on larger areas, and under ordinary circumstance of field cultivation, is instructive both by showing the comparative results which Mr. Sinclair obtained, and by stating and suggesting a great diversity of methods in the application of the manure.

Kind of Manure and Mode of applying it.	Manures, omitting Fractions. Quantity per acre.				Produce.	
	Dung in Tons.	Salt in Bus.	Lime in Bus.	Oil Cake in Bus.	Bus.	Weight of a Bus.
						lbs.
Spit manure applied previous to sowing the seed	45	-	-	-	49	57½
Salt and spit manure dug in salt mixed with seed	45	44	-	-	75	58
Salt mixed with soil four inches deep before sowing	-	44	-	-	91	59
Salt ditto ditto ditto	-	5½	-	-	77	59

Salt and oil cake mixed, and sown with the seed	-	5½	-	5½	60½	2
Salt and oil cake mixed, and applied as manure	-	5½	-	5½	74½	58
Salt, oil cake, and manure, applied as manure	90	5½	-	5½	74½	58
Salt, oil cake, and manure: the salt and oil cake sown with the seed, manure previously dug in	90	5½	120	5½	55½	55½
Salt, oil cake, and lime, applied as manure	-	5½	120	5½	71	51¼
Salt, oil cake, and lime, sown with the seed	-	5½	120	5½	55¼	55¼
Salt, oil cake, and lime, applied to the surface	-	5½	-	5½	66	58
Salt applied to the soil in preceding spring	-	62	-	-	44¼	57½
Salt applied to the soil in preceding spring	-	31	-	-	26½	47½

Salt acts well in many kinds of composts. Though highly antiseptic when somewhat freely applied to the surface of compact and homogeneous dead substances, yet it accelerates decomposition and multiplies the affinities for recombination when mixed in small quantity with incompact and heterogeneous dead substances; and hence it may be advantageously strewn over masses of farm-yard manure when they are carried to the field, or sprinkled, from time to time, upon accumulating heaps of the refuse of gardens and coarse vegetable matters and animal remains. A mixture of foul salt with grass roots and other rubbish harrowed off the land was long ago tried as an ingredient in compound manures, for a crop of barley and grass seeds, and found to exceed the most sanguine expectations. A mixture of salt with earths and shell sand, spread on turnip fallows, tells well both on the green crop and on the succeeding grain crop; and either this or any other application of salt, is supposed to increase the vigour and hardiness of turnips, and to enable them to withstand better the effects of frost. A compost of salt and lime, in the proportion of one measure of the salt and two measures of the lime, when properly prepared and judiciously applied, is an excellent manure for many purposes. The mixture of the salt and the lime should be made by simply intermingling them in a heap, and should either be covered with sods or kept in a shady place, and should be allowed to lie undisturbed during two or three months; and, in this way, it passes through a gradual decomposition, and resolves itself into muriate of lime and soda, and acquires an alkaline crust over its whole surface, and becomes one of the most powerful substances known for absorbing moisture from the atmosphere into the soil. Cuthbert W. Johnson, Esq., recommends it to be applied at the rate of from 35 to 60 bushels per acre, either sown out of a seed-basket, or mixed with earth and spread in the usual way; and he says respecting it, "It promises now, through the successful example of Mr. Bennett, and Sir C. Burrell, to be very generally adopted. It is difficult to account for the neglect of this manure, on any other ground than the difficulties which were so long thrown in the farmer's way, by the long continued tax upon salt. That it is not a novel plan for enriching the land is quite certain. Glauber, a celebrated German chemist, one of the last of the alchemists,

described it in the jargon of his craft nearly two centuries since; when he said.—'The sal mirabilis (common salt), as it is of itself, is, by reason of its corroding virtues, which it as yet retains, plainly unfit for the multiplication of vegetables, for that being so used would prove more hurtful than profitable. Upon this account it is necessary that to one part of it be added two parts by weight of the best calyx vine (lime), which being moistened with water and made into balls, are to be well heated red-hot for an hour, that so all the corrosivity being introverted, the sal mirabilis may be alkalizated, and used to vegetables for an universal medicine; for it conserves its attracting force, and loseth it not in the heating red-hot.' Christopher Packe, who, in 1688, published in English Glauber's folio volume, dwells at considerable length, in his preface, upon this mixture of salt and lime; 'for the enriching of poor and barren land, it is the cheapest of all mixtures, and is most easy to be done, for any ploughman having but once seen it done may be presently able to manage it.' Salt and lime was used as a manure by Mr. Mitchell of Ayr, many years since; and he, not knowing what others had done with this fertilizer before his time, considered himself to be the discoverer. He thus described his process:—'Take 32 bushels of lime, and slack it with sea-water, previously boiled to the saturated state. This quantity is sufficient for an acre of ground, and may be either thrown out of the carts with a shovel over the land in the above state, or made into compost with forty loads of moss or earth, in which state it will be found to pay fully for the additional labour, and is sufficient for an acre of fallow ground, though ever so reduced before. Its component parts are muriate and sulphate of lime, mineral alkalies in an uncombined state, also muriate and carbonate of soda. All the experiments have done well with it, but especially wheat and beans; and it has not been behind any manure with which it has been compared. There is one instance in which it was tried in comparison with 72 cart loads of soaper's waste and dung; and although this was an extraordinary dressing, yet that with this salt and lime manure was fully above the average of the field."

A mixture of salt with soot, and also mixtures of it with vegetable mould and with ditch scrapings, have produced excellent effects. "The mixture of salt with soot," says Mr. Johnson, "produces the most remarkable effects, especially when trenched into ground prepared for carrots. Mr. G. Sinclair found that when the soil, unmanured, produced 23 tons of carrots per acre, the same soil, fertilised with a mixture of only 6½ bushels of salt and 6½ of soot, yielded 40 tons per acre. Mr. Belfield describes the mixture as equally beneficial for wheat. And Mr. Cartwright found that when the soil, without any addition, yielded per acre 157 bushels of potatoes, dressing the same land with a mixture of 30 bushels of soot and 8 bushels of salt made it produce per acre 240 bushels."

"Mixtures of salt and earths," says Donaldson, "have been used with great benefit for turnips, and mixed and unmixed with farm-yard dung. The results were in every case favourable at the rate of 20 to 25 bushels an acre; and on carrots and potatoes the quantities of 13 and 9 bushels of salt were attended with very beneficial effects. In one case, 25 bushels were visibly much superior to 18 bushels on an acre; while for carrots, 6½ bushels exceeded 13½ in weight of crop under a similar application. In another set of experiments, on potatoes, we find 40 bushels of salt, one-half laid on in September, and the other half after the crop was planted, did not exceed in produce the quantity from the 20 bushels applied in September, and did not equal the usual crop from stable-yard dung alone, and that 40 bushels of salt applied with stable-yard dung did not much exceed the produce from the latter manure alone. These results are decidedly against the effects of salt; further experiments, on onions, carrots, turnips, potatoes and mangel-wurzel, showed a regular increase in the produce of all the articles, as the quantity of salt applied was diminished."

Salt has been applied to all sorts of grass lands, in various ways, in various quantities, and for various purposes, in most parts of Britain; and though very diversified in effect upon the quantity of produce, it has always, when moderately and wisely used, been highly beneficial in effect on the quality. From 6 to 16 bushels per acre have been very commonly used for the purpose of general fertilization, and have been generally found to improve both the quantity and the quality of the herbage, to kill the least refractory kinds of weeds, and to purify and sweeten the whole soil and sward; and from 20 to 40 bushels have been often used to destroy rank growths of mosses, nettles, ragworts, thistles, rushes, or other refractory weeds, and have sometimes killed for a time all the useful as well as the noxious plants, and have at other times but temporarily subdued the weeds, and proved of very small eventual efficacy. "It has been proved by experiment in Cheshire," says Sir John Sinclair, "that, after draining sour rushy land, if salt be spread upon the surface, in the month of October, its effects on the crop of next year will be in the highest degree satisfactory. In one spot, where 8 bushels were spread, a most flourishing crop of rich grass appeared in the month of May, but a still stronger crop in the month of July, where 16 bushels had been applied. In the Netherlands, Dutch turf ashes, which are strongly impregnated with saline particles, are applied to the second as well as to the first crop of clover, with great success; and Mr. Hollinshead strongly recommends sowing 6 bushels per acre on meadows, after the hay is

got in, particularly in dry and hot summers, and upon limestone and sandy soils. The moisture which the salt attracts and retains, powerfully assists vegetation, and produces a crop greatly superior in quality to that obtained by the application of dung. For meadows it is found to be an advantageous practice, to mix 16 bushels of salt with 20 loads of earth per acre, turning over the heap two or three times, that the substances in it may be thoroughly incorporated, and spreading it on the surface either in summer or spring."

The uses of salt as a manure in gardens, altogether additional to its uses in destroying slugs and worms and larvæ and weeds on lawns and gravel-walks and worked beds, are very numerous and valuable. It acts well, in the kitchen garden, for carrots, parsnips, turnips, onions, asparagus, and other similar crops; it prevents the clubbing of the roots of some of the brassicas; it promotes the vigour and beauty of all the many bulbous-rooted flowering-plants which naturally love habitats in the near vicinity of the sea; and it forms an excellent ingredient in composts for carnations and some other finely flowering fibrous-rooted perennials. A little salt dissolved in the water in which cut flowers are kept, is well known to prolong very considerably their duration; and a little salt mixed up with the compost of the flower-beds of the border and of the flower-pots of the greenhouse, might probably be found a pretty general promoter of both the beauty and the prolonged bloom of flowers.—*Hollinshead on the Importance of Salt as a Manure.—Sir John Sinclair on the Uses of Salt for Agricultural Purposes.—Hannam's Essay on Manures.—Johnson's Essay on Salt.—Johnson's Farmer's Encyclopædia.—Darwin's Phytologia.—Donaldson's Treatise on Manures.—Dana's Muck Manual.—Gregory's Outlines of Chemistry.—Turner's Elements of Chemistry.—Fennel's Use of Salt to Man and Animals.—Dacre's Uses of Salt as a Condiment, and other Papers by other authors, in the Q. SALT MARSH. See MARSH.

SALTPETRE. See NITRATES.

SALT-TREE. See CARAGANA.

SALTWORT,—botanically *Salsola*. A diversified genus of plants, of the goosefoot family. It has inferior, five-petaled flowers, fleshy calyxes, closed and calyx-embedded capsules, and spirally embryoed seeds. One species grows wild in Britain; about 15 species have been introduced from other countries,—principally Siberia and the South of Europe; and between 30 and 40 more are known. Three of the introduced species are slightly tender evergreen undershrubs; and all the rest are curious weedy-looking annuals, varying in height from a few inches to about 3 feet.

The common or prickly saltwort, *Salsola kali*, is an annual indigen of the light sandy sea-shores of Britain. Its stems are spreading, bushy, hairy, and about a foot high; its leaves are narrow and somewhat rugged, and terminate each in a sharp bristled point, and form an armature upon the stems; its flowers are solitary, minute, and flesh-coloured, and have coloured membranous edges on their calyxes, and bloom in July and August; and its fruit are turbinated, winged capsules, filled with spiral seed. This is the best of our native plants for yielding kelp, barilla, potash, and soda; and was formerly collected, in considerable quantities, on our western coasts, and burned to yield soda for the manufacture of glass and for other purposes. Yet though it grows freely from seed, and does not require any great nicety of management, it does not seem to have ever been made the subject of careful cultivation.

The cultivated saltwort, *Salsola sativa*, is a native of Spain, and was introduced to Britain about 65 years ago, and has pink flowers, and attains a similar height to the British species. The soda saltwort, *Salsola soda*, is a native of the South of Europe, and was introduced to Britain in the latter part of the 17th century, and has white flowers, and attains a height of about 3 feet. These two species are cultivated on the light sandy soils of the northern sea-board of the Mediterranean, and particularly on the coasts of Spain, for furnishing the barilla and the soda of commerce; and they afford the best kinds of these substances anywhere used in Europe. Why has not the cultivation of them been fairly tried in Britain? See the articles BARILLA and SODA.

SALTWORT (BLACK). See MILKWORT.

SALVIA. A large genus of ornamental plants, of the labiate order. Two species grow wild in Britain; about 140 species have been introduced from other countries; and about 100 more are known. A few of the introduced species are hardy annuals; a few are hardy biennials; many are hardy perennial-rooted herbs; some are tender evergreen herbs; a few are hardy evergreen undershrubs; and some are tender evergreen undershrubs. Most have a height of between 1 foot and 4 feet; very many have either blue, scarlet, violet, or white flowers; and the great majority possess a high degree of beauty, while some are among the most brilliant ornaments of the flower-garden. A medicinal species is noticed in the article SAGE; and the two indigenous species, and two aromatic exotic ones, are noticed in the article CLARY.

The spreading species, *Salvia patens*, is one of the most beautiful, and may be selected as a favourable specimen of the whole genus. It is a native of Mexico, and was introduced to Britain in 1838. It has a perennial root, and an erect and hairy stem, and commonly attains a height of from 2 to 4 feet. The leaves are large, ovate,

or deltoid, broadly hastate or somewhat cordate, or in some cases rounded at the base, and green and hairy on both surfaces. The flowers are disposed in long terminal racemes, usually branching into three at the base; and stand in opposite pairs, each at the axil of a small linear-lanceolate floral leaf. The flower-stalks are short; the calyx is from one-half to three-fourths of an inch long, hairy, green, and deeply divided into two lips; and the corolla is between 2 and 3 inches long, of a rich deep blue colour, with a broad gaping mouth,—the upper lip long, falcate, and erect,—and the lower one pendent, and having two lateral, oblong, reflexed lobes. This is a greenhouse plant; and loves a loamy soil; and varies much in the number, size, and brilliancy of its flowers, according to the degree of light and heat in which it grows; and, if weakened, or allowed to become etiolated, is liable to suffer great detriment to its beauty by disproportionateness between the length of its racemes and the mutual distances of its flowers.

Some of the most ornamental species, are, of hardy annuals, *S. trichostemoides*, 9 or 10 inches high, carrying blue flowers in May and June, and introduced from North America in 1826,—*S. prismatica*, about a foot high, carrying blue flowers in June and July, and introduced from Mexico in 1824,—and *S. horminum violacea*, about 20 inches high, carrying purple flowers in June and July, and introduced from the South of Europe toward the close of the 16th century; of tender annuals, *S. foliosa*, about 20 inches high, carrying blue flowers at any or all seasons, and introduced from Mexico in 1827; of hardy biennials, *S. ceratophylla*, about 2 feet high, carrying yellow flowers in July and August, and introduced from Persia in the end of the 17th century,—and *S. pinnata*, about a foot high, carrying purple flowers in July, and introduced from the Levant in the former part of last century; of hardy herbaceous perennials, *S. azurea*, about 6 feet high, carrying blue flowers in August, and introduced from Carolina in 1806,—*S. grandiflora*, 2 feet high, carrying light blue flowers from June till September, and introduced from the South of Europe in 1816,—*S. virgata*, about 4 feet high, carrying white flowers from July till November, and introduced from Armenia about 90 years ago,—*S. lyrata*, about a foot high, carrying light blue flowers in June and July, and introduced from North America in the former part of last century,—and *S. crassifolia*, about 2 feet high, carrying blue flowers in June and July, and introduced from the South of Europe about 44 years ago; of greenhouse herbaceous evergreens, *S. amarissima*, about 2 feet high, carrying blue flowers in July and August, and introduced from Mexico about 45 years ago,—and *S. pulchella*, about 2 feet high, carrying scarlet flowers throughout winter, and introduced from South America in 1821,—and *S. mexicana*, about 2 feet high, carrying scarlet flowers from May till July, and introduced from Mexico in the former part of last century; and of greenhouse ligneous evergreens, *S. aurita*, about 2 feet high, carrying blue flowers in May and June, and introduced from the Cape of Good Hope toward the end of last century,—*S. formosa*, about 4 feet high, carrying scarlet flowers from spring till the latter part of autumn, and introduced from Peru about 65 years ago,—*S. fulgens*, 4 or 5 feet high, carrying scarlet flowers from May till October, and introduced from Mexico in 1829,—and *S. confertiflora*, 3 or 4 feet high, carrying bright red flowers in autumn, and introduced about 12 years ago from the Organ Mountains of Brazil. But some of the unintroduced salvias are believed to be fully equal in beauty and splendour to the finest of the introduced ones; and probably so many as one hundred species or upwards, from America alone, may eventually be found well worthy of cultivation in the flower-garden. A curious hardy herbaceous species, which was introduced about 50 years ago from Germany—*S. glutinosa*, about 3 feet high, and carrying yellow flowers from midsummer to mid-autumn—is used in some districts of Switzerland for entangling and removing disagreeable insects, either by spreading the plants under beds, or by making them into a broom, and drawing this slowly and gently along the floor.

SALVING OF SHEEP. The application of a salve to the skin and wool of sheep, in order to destroy vermin, and to afford protection from the weather. The name given to it in Scotland is smearing. It is practised chiefly upon the mountain breeds,—and more upon the blackfaced breed than upon the Cheviots,—and more upon the Cheviots than upon the improved cross-breeds. The salve should be thick enough to be capable of being taken up by the finger, and at the same time thin enough to be easily rubbed off when drawn along the skin; and it is most facilely and efficiently applied while the sheep lies upon a stool of just suitable breadth and length to contain its outstretched body, and while the operator sits astride upon a narrow projection from one end of the stool. The wool is parted longitudinally into rows, without a pile being allowed to lie across them; the salve is applied directly to the skin along each bared row; and the rows should be perfectly parallel to one another, and at such distances that the deposition of salve along each may reach through the bottom of the piles to the deposition along the next, so that the whole skin may be equally salved and every individual pile anointed. No portion of salve, however, ought anywhere to touch the wool except at its roots. An experienced operator can salve from twenty to twenty-five sheep in a day.

"Salving," says the editor of the Quarterly Journal of Agriculture, "was most probably first adopted with the view of healing or preventing that vile cutaneous disease called scab,

and of destroying vermin. From the treatment that sheep received in this country until a comparatively recent date, it is probable that that disease was of usual occurrence every spring. Sheep got leave to traverse the pastures all winter without shelter, and with no food but what they could pick up from coarse grasses, or what they could scratch up from under the barest patches of snow. When the pasture revived in spring, the condition of the sheep recovered, and the recovery was sudden, and thereby attended with eruption on the skin. The constant and uneasy itching occasioned by the scab impelled the sheep to rub themselves against any object that presented itself in the most convenient form for the purpose; and the consequence of the rubbing was the tearing off, in shreds, the fleeces long before the season for clipping arrived. According to the authority of Culley, fine-woolled sheep existed in Scotland before the introduction of the coarse-woolled blackfaced breed; and as there would of course be a natural desire to preserve the fleece from such destruction, salving became the proposed remedy. Another remedy of a more natural character was, perhaps, simultaneously proposed, and that was the introduction of a hardier race of sheep, whose fleece could withstand the bleaching effects of rain, and the chilling effects of storm better than the fine-woolled old breed, and hence the introduction, it is said, of the blackfaced breed into Ettrick Forest, by one of our Scottish kings. But even they, with all their hardihood of constitution and coarseness of wool, were found unable to withstand the inclemency of the winter storms in our hills; and hence smearing was resorted to with them as well as the older fine-woolled breed. But what was the best salve to apply for the purpose? Tar, it was thought, would mat the wool together and keep out cold; and grease, it was conceived, mixed with it, would mollify its astringent effects both on the wool and the skin. And so this smear of tar and butter has long been used for the purpose; and to make it as cheap as possible, filthy salted and adulterated butter has been imported from Germany to mix with the tar. The salt in this butter deliquesces, and keeps the wool always in a raw damp state. The smearing with this stuff was so long persevered in, that the manufacturers will no longer buy the clotted stuff called 'laid wool,' but at a great reduction of price. In that state the wool is found altogether unfitted, from staining, for the manufacture of white goods; and even when washed as well as can be, it resists the more brilliant dyes to which it may be subjected. On this account, many expedients have been devised to dispense with the use of tar and salt grease-butter, and to substitute something possessing the adhesive properties of tar and the emollient properties of butter. The objects chiefly aimed at in smearing sheep, now that they are kept tolerably free of the scab, is the protection of the animal from cold, the destruction of the vermin which at times infest them, and the increased growth of the wool,—all desirable objects undoubtedly; but the question is, can these be best attained by salving or other means?

"The answer to this question requires some consideration; but the analogy derived from the management of sheep in the low country may assist us to a satisfactory one. In the first place, there can be no doubt that, were the winter-pastures of hill-sheep sheltered as they ought to be, the sheep would require no other protection from the weather. The rain, as things are, no doubt, washes away the natural grease from the wool and renders it harsh, which the grease of the salve tends to soften; but were the sheep sheltered by means of plantations, the rain would not have the same power to deprive the wool of its natural grease. There is another condition in the management of sheep which would supply an adequate quantity of natural grease to the wool, and that is by keeping the sheep always in a fair condition. This could be accomplished by a plentiful supply of good food in hard weather, consisting either of meadow-hay, which might be obtained by means of irrigation in every valley among the hills; or, by associating arable farming with hill-pasturage, turnips could be raised to support the sheep in winter along with the meadow-hay. Is it not better to supply grease to the wool in the natural way, through the skin, than by any artificial application upon the skin? and would not a fair condition of the carcass supply an adequate quantity of natural grease?

"But it may be objected to all this, that the proposed management of hill-sheep would be attended with great labour and expense. No doubt the first attempt of the plan would be attended with much trouble and a good deal of expense; and on that account it should chiefly be undertaken by landlords or by tenants of capital effecting it under encouraging leases. But we would ask in return, has the plan ever been attempted? and if not, how can it be known that it is one which would not repay the cost? Would 5s. be considered an extravagant increase of the price of a carcass of mutton, after being better fed than it has hitherto been accustomed to? and would 2s. a-fleece be considered an exorbitant increase of price, were the wool improved in quality and presented in such a state as is desiderated by the manufacturer? Would not, therefore, 7s. a-head increase of value over the many thousands of sheep which depasture on our mountain-ranges, afford to cover a good deal of extra expense in sheltering and feeding them with plenty of food in winter? And would not the proper shelter of pasture in winter very much improve it for the summer? The lesson derived from the successful management of sheep upon the plains should not be neglected. It

warrants us in believing that hill-sheep could be maintained in condition, and that without smearing, though some application at stated times seems necessary to destroy the vermin on sheep. Indeed, we are convinced, that were this plan but partially adopted at first, it would soon show the practicability of maintaining finer woolled sheep upon our mountain-pastures, and of their superseding the coarse-woolled variety altogether.

"But until these changes are effected, and they will be some day we have no doubt, smearing, we suppose, must be persevered in; and the question that most concerns us in the mean season is, what is the best sort of salve for sheep, that is to say, what sort of salve will best protect sheep from the chilling effects of rain and snow,—which will most easily destroy the vermin on sheep,—and which will best encourage the growth of wool, and at the same time preserve it in a soft state, and free from all stain? To ascertain these important points, the Highland and Agricultural Society has offered a premium for the best account of a comparative trial of two kinds of salve,—first, one made of crude white arsenic, butter, soap, turpentine, &c.; and, second, another of white tar, which is common tar, deprived of its colouring matter, and cocoa-nut oil, mixed in the proportion of common tar and butter. We believe that favourable accounts of the safe application of both these salves have been received by the Society. For our parts, we have so utter an antipathy to the use of arsenic, in any shape, about a farm-steading,—and the precautions advised to be adopted in the use of it, to prevent its entering the eyes, ears, and mouth of sheep, show there is danger in using it,—that we would not use it, nor advise any one to use it, on any account, however beneficial its effects may be proved to have been; and besides, we are not satisfied, on the common sense view of the thing, that the application of any mineral substance can be beneficial to wool, however it may preserve or even improve its natural colour. With regard to the white tar-salve, we have heard from extensive store-masters, that though it keeps the wool free of discoloration, and in this respect is superior to the common tar, the wool gives a very light clip wherever it is used."

"All the European tars, especially that from Norway," says Mr. Hogg of Stobohope, "have been remarkable for their blackness, strength, and drossiness. This last adjunct is not discernible till the finer and more soluble part of the tar has, along with the greasy part of the mixture, and by the heat of the animal's body, been diffused round the carcass. It then appears in a clammy, clotted condition among the wool, where it rests till spring. The heat of the season now dries it into a mouldering state; and it is principally this tarry dreg which gives that zone of pollution to the fleece for which tarry wool is so much hated. But this dirty sediment, though detestable in its final consequences, is the main material which closes the wool, and keeps it firm and compact round the animal in the greatest tempest. When the American tar began to be used, it was whiter, milder, and softer, not so searching for the constitution, and far more free from sediment than that from the north of Europe; but just as the store-master was about to make this tar the basis of a smearing composition, the country was all at once inundated with white new salves, sundry of them containing no ingredient which could be serviceable either for sheep or wool. The materials of others were purposely kept a secret, the inventor persuading himself he would make a fortune by the discovery; but, alas! they have scarcely maintained a character for one year. Yet there is no want of a new supply; for, like the many-headed hydra, no sooner is one dismissed as useless, than another starts up in its place, generally with some epithet in its designation expressive of superiority. * * * Except with the excessively parsimonious or careless store-master, the new, white, cold mixtures never can come into use as salves for smearing. With the former, the cheapness of the materials and the facility with which they can be applied, will, no doubt, be an inducement for their continuation; with the latter, that natural apathy or sluggishness, which disposes to neglect other improvements, will also induce him to disregard this; but by the judicious, the active, and the anxious store-master, they cannot be long employed in the form in which they are at this time presented. Every one of them, without exception, is destitute of any ingredient, or at least contains it in very small quantity, which is calculated to close the fleece previous to the setting in of winter; and the principal benefit derived from smearing is keeping the animal warm and comfortable during the rigours of that season. To make this more obvious to the inattentive farmer, I may observe that nature does a great deal in furnishing the animal with wool preparatory to the setting in of winter. It grows in that direction, and in the appropriate quantity, where the wearer needs it most for defence and clothing; and each pile of wool, as it grows (at least in a thriving sheep), is anointed with an unctuous oily secretion, which holds every fibre of wool in its place and beside its fellows. This natural cement is sufficient to throw aside the rains and mists which, through summer, visit all alpine pastures; but, for the snow drift, incessant rains, and tempests of winter, it is insufficient as a defence; and the artificial unguent, composed and applied by man, comes to its assistance. This extinguishes the natural oil; and, by imperceptible advances, at least if a sheep is rightly smeared, creeps to the top of every pile of wood; and, if it have not some tenacity in its composition, it is good for nothing—nay, it is worse; it

destroys the natural juice in the wool, and is incapable of again closing it against winter. By the destruction of the natural yolk, the filaments of wool have not only lost their original connection, but, in order to deposit the artificial salve, the wool must be perfectly and completely opened to the bottom, where the thin white salves are employed. This opening never again closes up. The superior flakes of wool, indeed, overlie the inferior; but they never coalesce and intermingle as they did formerly. From these statements may be inferred the extreme necessity there is for using a right salve, or one which will keep the poor creature warm and comfortable through winter; and its wool being rendered compact and firm around it, contributes more to this purpose than any other means which can be employed."

"As a remedy to many of the evils incident to the prevailing modes of salving sheep," said Mr. Robert Boyd, of Innerleithen, in 1843, "Mr. Ballantyne of Holylee, a zealous labourer for the improvement of the fleece, has, for the last two years, salved his flocks, which amount to upwards of 163 scores, with the following composition:—

30 lbs. of butter, ...	5d.	£0	12	6
14 " rough turpentine, .	1½d.	0	1	9
3 " black soap, . . .	4d.	0	1	0
2 " soda ash, ...	1d.	0	0	2
5 bottles refined spirit of tar,	7d.	0	2	11
		£0	18	4

To this 21 pints of water are added, to assist in the equal spreading of the mixture. The above composition is found sufficient to salve 100 sheep, which is at the rate of 2¼d. a-head. It requires to be applied to the fleece at a temperature a little above blood-heat. When we consider the chemical nature of this composition, it will appear that the most appropriate name which can be given to it, as a new salve, is 'artificial yolk,' for it is of the same nature, and possesses the same properties, as the natural yolk existing in the wool. It is known that the conducting powers for heat, both of animal and vegetable oils, are very materially diminished when saponified; this is owing to the compound being thus rendered porous. The soda-ash contained in the above composition has the effect of saponifying the whole mass; consequently, the conducting power for heat of the animal oil contained in it is greatly diminished, and a degree of comfort obtained for the animal to which the composition is applied which could not result from the use of oils which had not undergone the process alluded to. It was supposed by some that, owing to the saponaceous nature of this composition, it would, in some measure, be liable to be washed off by rain. This, however, has been proved not to be the case; for it was found, on the strictest examination, that no aqueous matter had been able to penetrate the fleece during its growth. Mr. Ballantyne considers the artificial yolk salve decidedly superior to any other he has ever used as a defence to the sheep. In addition to this, it is calculated, in my opinion, to produce a fleece unequalled in the history of salves. In this estimate of its value, I have the concurring testimony of Mr. Barff, wool-stapler, Wakefield, whose extensive experience entitles his opinion to great weight. He has been the purchaser of Holylee clip for the last twenty years; and he affirms that the salve used by Mr. Ballantyne for the last two years has had the effect of producing upon the fleece an indescribable kindliness to the touch, and that its felting properties were also very materially improved. In consequence of these advantages, he has allowed Mr. Ballantyne the highest price he gives for the purest unlaid wood, which is the best evidence that can be adduced of his high opinion of its value. It may be further added, that the opinion of the English wool-staplers appointed to decide upon the merits of the Leicester fleeces, shown in competition at Edinburgh in 1841, was expressed in terms of commendation in reference to the fleeces in question."

SAMBUCUS. See Elder.

SAMOLUS. See Brookweed.

SAMPHIRE,—botanically *Crithmum*. A small genus of herbaceous plants, of the umbelliferous order. The common or sea samphire, *Crithmum maritimum*, is a perennial-rooted indigen of the coast-rocks and sea-cliffs of Britain. The root comprises many strong fibres, which penetrate deep into the crevices of the rocks; several fleshy, succulent, leaf-garnished stems rise from the root to the height of 12 or 20 inches; the leaves are twice ternate, and stand on sheathing footstalks; the leaflets are lanceolate, acute, fleshy, and nearly half an inch long; and the flowers are produced in dense circular umbels at the top of the stems, and have yellow anthers and white petals, and bloom from July till September. This plant has very long been in high request for making an agreeable pickle, and provoking an appetite for food, and has also the reputation of being a diuretic and of removing obstructions of the viscera. It commonly grows on spots which cannot easily be reached; and is often gathered by poor peasants or fishermen, who scramble perilously on the cliffs, or are still more perilously let down by ropes; and, at a time when it was regularly supplied to the markets of large towns, it was frequently and even commonly substituted by plants which resemble it in appearance but are totally destitute of its good properties. Some serious consequences have followed the practice of pickling and cooling it in copper pans. It cannot without difficulty be preserved in gardens, and will nowhere grow so vigorously in them as on sea-cliffs, yet may be kept for some years, and made to thrive tolerably well, by being planted on a moist gravelly soil. It can be propagated either by radical division or from seeds.

SAMPHIRE (Marsh). See Glasswort.

SAMPHIRE (Prickly),—botanically *Echinophora spinosa*. An indigenous evergreen herb, of the umbelliferous order. It occurs on the sandy sea-shores of some parts of England; but is exceedingly rare. Its root is long, fusiform, and fleshy, and has the flavour of a parsnip, and possesses stimulating and diuretic properties; its herbage is glaucous and finely downy, and branches profusely, and spreads 2 or 3 feet on all sides; its leaves are rigid and doubly pinnatifid, and have entire, awl-shaped, spinous leaflets; and its flowers are white and bloom in July.

SAMPLE. A small quantity of grain or of any other commodity, exhibited at a public or a private market, as a specimen. See the article Market.

SAMYDA. A genus of ornamental, tropical, evergreen, calyciflorous shrubs, constituting, with the genus Casearia, the natural order Samydeæ or Samydaceæ. They have alternate, stipulate, entire leaves, covered with pellucid dots,—and axillary flowers, of no great beauty,—and fruit of somewhat similar structure to that of the Bixineæ and the Flacourtianeæ. Eight or nine species of Samyda, varying in height from 3 to 8 feet, and most producing white or greenish flowers, and all propagable from cuttings, have been introduced to the hothouse collections of Britain; and about as many more are known.

SAND. Disintegrated, granular, mineral matter. It results either from the separate deposition of silicious substances in the course of the formation of alluvium,—or from the mutual attrition of fragments of granular rock under the running action of water,—or from the comminution and commixation of corals, shells, and boulders under the littoral refluxions of the sea. Some vast beds of it belong to remote geological periods; and others are in constant course of deposition at the present day.

Sand is exceedingly diversified in constitution; it cannot be logically distinguished from other finely divided mineral deposits, such as clay and chalk, by any less general character than merely its granular or crystalline and incoherent structure; it possesses every variety of composition which could result from the disintegration of the most opposite kinds of granular minerals, and from the deposition of their water-worn debris under the most widely different circumstances; and it is in some places chiefly silicious,—in others, largely argillaceous,—in others, largely calcareous,—and in others, a combination of any of these characters either with one another, or with the multifarious earths and organic remains which commonly abound in alluvium. Yet any considerable intermixture of argillaceous matter, makes it nearly allied to loam; any considerable intermixture of calcareous matter either makes it nearly allied to marl, or gives it the name of shell-sand; any considerable mixture of other earths or of organic remains, either makes it nearly allied to alluvium, or gives it the name of sandy soil; and only when it consists very predominantly or quite characteristically of silicious matter, does it constitute ordinary or tolerably pure sand,—and then, not only is it granular and incoherent, but it consists, in fact, of irregular quartz crystals, and has a near relationship to flint. See the article Silex.

Silicious sand is often classified, for economical purposes, particularly for those of the farm, into sea sand, river sand, and pit sand. Sea sand, except when it possesses such an intermixture of calcareous matter as not to be strictly silicious, is generally the worst for any purpose; river sand is commonly good for some kinds of mason work; rivulet sand, but especially sand from the gentle washing of roads, is often the best for applying manurially to land; and pit sand is so exceedingly diversified in constitution as to be, in different specimens or in different circumstances, either good, bad, or indifferent for almost any use to which silicious earth is applied. Most alluvial or loamy or argillaceous or calcareous sands are well fitted to act as fertilizers when used with due discrimination; yet some are so ferruginous or slaty or otherwise infertile as to be either useless or positively pernicious.

Sand-drift, in both its silicious and its calcareous varieties, and in both its loose and its consolidated states, is sufficiently described in the article Downs. A vast tract of moving and destructive sand-drift on both sides of the embouchure of the Garonne, in the south-west of France, was reduced to fixture, in the early part of last century, by the simple expedient of flanking it with a great breadth of young plantation of the *Pinus maritima major;* and a considerable and desolating tract, on the north-west coast of Ireland, was converted, not very many years ago, into actual profitable pasture for both sheep and cattle, by the still simpler expedient of planting it, in small rectangular holes, with little fan-shaped tufts or bunches of the sea-reed or mat-grass variously known as *Arundo arenaria, Psamma arenaria,* and *Ammophila arundinacea.* The sea-reed, in fact, is the best known binder of sand-drift; the *Elymus arenarius* is next to it; the *Carex arenarius* is next; and then follow *Agropyrum junceum, Festuca rubra, Galium verum,* and *Trifolium repens.* See the article Arundo.

Sand lands or pure sandy soils are such as consist very predominantly of silicious sand. They are either whitish, blackish, reddish, yellowish, or greyish; and they vary, in the size of their granules or the comparative comminution of their substance, from mere dust to absolute gravel,—but, in general, have a medium texture between these extremes. The black, the grey, and the ash-coloured are the most infertile, and occur principally on heaths, on commons, and in absolute deserts. Arable sand lands, when wet, feel firm under the foot, and are harsh and grat-

ing to the touch, and admit of being ploughed into tolerably coherent furrow-slices; but when dry, feel soft to the tread, and are dissipative to the touch, and yield beneath a very small weight, and are liable to be blown away with the wind. All sand lands acquire a high temperature in summer, and are exceedingly irretentive of moisture; and many naturally abound in bents, heaths, quick grass, sorrel, broom, and furze. The best means of improving them are copious intermixtures of marly or argillaceous earth; and the crops most suitable for them are carrots, parsnips, turnips, rye, and oats. See the articles MANURE and SOIL.

Sand, of a silicious kind, particularly such as is washed from hills and roads and found in the bed of rivulets, is an excellent application for rendering clay soils loose and friable; and, when used as litter in cattle sheds, or as a carpeting for fold-yards, or in any other capacity which causes it to be saturated with liquid or semi-liquid excrements, forms a very good manure for most kinds of cold stiff land. But, as a mere textural improver, it requires to be as thoroughly as possible incorporated with the soil, and always does best when either itself or the clay to which it is applied contains some proportion of calcareous earth; and as a litter for cattle-sheds and fold-yards, it is often inconvenient on account of its weight, and always does best when it contains so large a proportion of clay or of vegetable remains as to be far more truly a loam or a mould than a sand.

Shell sand, or calcareous sand, abounds in many parts of the eastern, southern, and south-western shores of England, of the southern and south-western shores of Ireland, and of the western shores or western islands of Scotland. It differs much in colour, and in quality, and in the circumstances under which it is found or can be obtained by farmers. Some kinds of it are a finely comminuted dust, scarcely distinguishable in appearance from the most powdery sorts of drift-sand or of sandy soil,—and other kinds are more or less granular, or even contain intermixtures of bits of shells and small boulders. Some are in a very large degree or even mainly calcareous; and others contain great proportions of silicious and argillaceous and other earths. Some appear to derive their calcareous matter entirely from the fracture and crumbling of shells of the present epoch; and others seem to derive more or less of it from calcareous marine deposits, or calcareous marine formations, either molluscous or coralline, of comparatively remote geological periods. Some lie loose and dry and perfectly accessible along the beach; and others lie always within low-water mark, or even under considerable depths of the sea, and can be procured only by dredging.

Calcareous sand, in almost all its varieties, is a valuable manure for clay soils, heavy loams, and spongy and mossy lands, and an excellent top-dressing for rough sour pastures and meadows. It also does well to be mixed in composts for lighter soils; and may, in some cases, be very advantageously used for littering cattle, or strewing folds and sheds. "An economical use of shelly sands, separately or in composts, may be recommended in laying the manure on leys one year before ploughing, that it may have time to raise a grassy sward, and get fixed and incorporated with the surface among the roots and fibres. An application to wheat fallows has been recommended; in that case, it should be applied late in the season of working the land, and be lightly covered."

A valuable calcareous sand is extensively employed in Brittany under the name of marl, and consists principally of the remains of shells, madrepores, and corallines, but also contains a small proportion of highly azotised organic matter, and of course is, on that account, all the more mightily fertilizing. It occurs in great abundance at the mouths of the river of Morlaix; and is there the subject of a considerable traffic; and is obtained by dredging from barges, between the middle of May and the middle of October; and is said to be reproduced from time to time in a constant series of new banks. It is applied to light dry soils in doses of from 5 to 6 tons per acre, and to clayey lands in doses of 11 or 12 tons; and it requires to be used as soon as possible after it is taken from the sea,—for, when long exposed to the air, it suffers disaggregation, and loses a portion of its good qualities.

Shell sand, of very similar constitution to that of Brittany, abounds in some parts of the sea-margin of Cornwall and Devonshire, and has for many ages been appreciated by the farmers of the adjacent sea-boards. A vast and seemingly inexhaustible supply of it occurs in the estuary of Padstow; and was formerly carried some miles into the interior on horses' backs and in carts; and is now transported to greater distances and in ampler profusion by railway. This rich deposit was declared free from toll for the use of farmers, by a public document of the 13th century; and again was pronounced by a statute of the seventh year of James I., "to be very profitable for the bettering of land, and especially for the increase of corn and tillage within the counties of Cornwall and Devon." The sand is dug out of the shallows of the estuary, and carted thence to the shore, and heaped up there in large depots for transportation into the country; and from one point, at Wadebridge, it is carried into the very heart of Cornwall, and distributed off in two branch directions, by a railway which was planned and executed mainly or almost solely for the purpose; and it has, in consequence, become diffused far and wide as an ordinary manure over the county, and has produced the most extraordinary effect on the fertility of its surface. Mr. Herapath has furnished the following account of the sea-sand, felspar,

and corallines of Devonshire to the 'Pharmaceutical Times':—"The calcareous sea sand which collects in vast quantities in many parts of the Devonshire and Cornish coasts is, as is well-known, most extensively employed by the agriculturists of those counties as a manure. In such high estimation, indeed, is this sand held than many thousands of tons of it are annually conveyed from the sea-side to be applied to the lands in the interior. It is generally preferred by the farmers to cart away directly after the receding of the tide, when it is completely saturated with the sea-water, the salt of which must, of course, materially increase its value as a manure. It has been found by them to produce the most beneficial effects on close clayey soils, which it opens and renders more porous, and thus enables the water and atmospheric air to have a freer access to the roots of the plants, and, at the same time, facilitates the drainage of the land. The sand which I subjected to analysis was obtained from Barracaine, a small cove within a few miles of Ilfracombe. It contained in a 100 parts:—

Water	0·500
Soluble salts, consisting chiefly of chloride of sodium, sulphate of soda, and magnesia, with minute traces of potash	0·300
Organic matter	2·420
Carbonate of lime	47·438
Carbonate of magnesia	0·097
Sulphate of lime	Very minute traces.
Phosphate of lime	0·025
Oxide of iron Alumina	0·460
Sand, silica, and debris of slatey and granitic rocks	48·760
	100·000

Twenty grains of the sand when burnt with potash and lime gave of ammonia chloride of platinum 0·58 grs.—0·1845 per cent. of nitrogen —0·2240 grs. of ammonia. The traces of potash observed in the soluble salts were without doubt derived from the decomposition of the felspar, of which a pretty large proportion of the substances insoluble in hydrochloric acid consisted. This felspar would become gradually disintegrated by the combined influences of air and moisture, and yield up its potash to the soil, which it would improve to that extent, rendering it better suited for the cultivation of grain crops. A fine specimen of this mineral, from the same locality, was found upon analysis to consist of

Silica	64·109
Alumina	19·013
Lime	0·500
Magnesia	Very minute traces.
Oxide of iron	traces.
Potash	16·277
	99·899

By acting upon some of the same felspar partially decomposed and in fine powder with boiling hydrochloric acid, &c., as recently proposed by Fownes, I was enabled to verify the statement of that gentleman with regard to the presence of phosphoric acid in this mineral. Evident traces of the acid could be detected in 500 grains of the powdered mineral. The carbonates of lime and magnesia, and phosphate of lime, contained in the sand, are principally derived from comminuted shells and corallines, as may be easily proved by an ocular examination. Some specimens of the corallines from Budleigh Salterton, on the same coast, were found to contain in 100 grains as follows;

Soluble salts	traces.
Organic matter	9·040
Carbonate of lime	84·257
Carbonate of magnesia	1·373
Sulphate of lime	traces.
Phosphate of lime	0·100
Oxide of iron	0·820
Silica and sand	2·400
Fluoride of calcium	minute traces.
Water and loss	2·010
	100·000

Twenty grains, when burnt with potash and lime, gave of ammonio-chloride of platinum 2·17 grs—0·689 per cent. of nitrogen, or 0·837 gr. of ammonia. These corallines are now very largely employed in commerce in the manufacture of Barkers' patent sub-marine manure, of which they form one of the principal constituents. Previously to mixing them with the sea sand, night-soil, decayed fish, &c. which compose the other ingredients of this manure, they are heated with about an equal quantity of common salt, which effectually disintegrates them, and renders their constituents in a more fit state to be assimilated by plants."

A sand somewhat similar to that of Padstow is employed by the farmers of the north-east of Norfolk; and is much appreciated as an immediate and durable fertilizer of clay soils. An enormous and continually renewing deposit of calcareous sand, probably as much of very ancient as of modern origin, and everywhere so comparatively free from admixture as to seem entirely composed of powdered shells, comminuted corallines, and dust-like organic matter, extends along a large portion of the great outer Hebridean group known as the Long Island; but has as yet been comparatively little used for manurial purposes; and, in many great tracts, it has even drifted itself so freely and lightly and prodigiously over a vast extent of the poor, thin surface of the low, bleak, tempest-lashed islands, as to annoy and bewilder the landowners in nearly the same way as the west-of-Ireland sand-drifts. A large deposit, of great value, and very favourably situated along a finely arable seaboard, extends over a great part of the south-western sea-margin of Ireland. A deposit, somewhat remarkable for being on the east coast of Scotland, and for containing some intermixture of pretty large stones, both silicious and argillaceous, occurs on the sea-beach, near Gosford, in East Lothian. "In the greater part of the

Hebrides, Inner and Outer," says Mr. Clark of Ulva, "shell sand is to be found; and if used along with the kelp weed which there abounds so very much, crops of potatoes, bere, and oats might be raised more than sufficient to supply the wants of the dense population of these islands, and render them independent of the supplies of meal which they annually import from the Low Country." Transportations of it, either from entirely barren districts, or from districts where it is little appreciated, to some fine agricultural districts at even such remote distances as 150 or 200 miles, might in many instances be found both enriching to the proprietors and promotive of the general interests of agriculture; and such a traffic on a small scale, and to comparatively short distances, was begun a number of years ago, in some parts of the Hebrides.

Sea-sand of an entirely different kind from all ordinary calcareous sand, yet scarcely inferior to it in fertilizing power, occurs in some low and slightly sloping beaches which are rich in cockles, mussels, and other molluscs. This sand of itself may be principally silicious; but it contains so considerable a proportion of organic matter, and particularly of broken shells and living molluscs, as to be more or less powerfully manurial. A sand of this sort is used, with excellent effect, by the farmers all around Morecambe Bay, as a material of composts for their wheat and barley crops,—commonly in the proportion per acre of about 26 small one-horse carts of the sand, about 4 of lime, and about 10 of farm-yard manure.

SANDAL-TREE,—botanically *Sandoricum Indicum*. An Indian, white-flowered, evergreen, timber-tree, of the order Meliaceæ. It constitutes a genus of itself. It has naturally a height of about 40 or 45 feet.

SANDAL-WOOD,—botanically *Santalum*. A genus of exotic, ligneous, monochlamydeous plants, constituting the type of the natural order Santalaceæ. The plants of this order are either trees or shrubs or herbs, with inconspicuous and uninteresting flowers; and most are natives of India, Australia, and Southern Africa,—and the rest of Europe and North America. Six or seven hardy herbaceous species, 7 or 8 hardy ligneous species, and 8 or 10 greenhouse and hothouse species have been introduced to the gardens and botanical collections of Britain. Only 3 or 4 of the introduced species belong to the sandal-wood genus; but one of these, *Santalum album*, is the most interesting in the whole order. This plant is a tall evergreen shrub, or small evergreen tree, of India; and furnishes the well-known white sandal-wood of commerce. This wood has a slightly bitter taste, and a sweet aromatic flavour; and possesses mild sudorific properties; and is in considerable request as a perfume. It is used by the people of India, also, for a variety of medicinal purposes, and as a material for small articles of fancy cabinet-work.

SANDBOX-TREE. See Ajuapar.

SANDCRACK. A perpendicular crack or fissure on the side or quarter of the horse's hoof. In the fore-feet, it almost always occurs on the inside, on account of that part being the weakest; and in the hind-feet, it sometimes or even commonly occurs in the toe. In some cases, it does not extend to the sensible parts; and in others, it somewhat strongly affects them, and causes considerable lameness. It arises sometimes from a constitutional or a temporary brittleness of horn,—sometimes from such a tread or other injury as impedes the secretion of the horny matter of the hoof,—and very generally, in the case of the fore-feet, from such an unnatural elevation of the toe as occasions the horse, in acts of special exertion, to make a great pressure on the point at which the crack occurs. The common therapeutic treatment of it is to separate the divided part of the hoof from the growing part with a rasp or a firing-iron, and, i no inflammation be present, to seal up the place with some pitchy compound, and to chamber out the substance immediately beneath so as to produce relief from the pressure of the shoe. But Mr. Blaine recommends, as an additional means of completing the cure, and of preventing the formation of a new crack or disjunction before the growth of horn is perfected, to smear some melted shoe-maker's wax all over the hoof,—to bind neatly, evenly, and firmly upon it, while it is yet liquid, about 3 yards of tape, in such a way as to include as much of the hoof as may be within the turns,—to fasten off with a hard knot,—to smear the whole over again with more wax,—and to smooth it all to an even surface, and rub it over with a little lard or other greasy substance.

SAND-DRIFT. See Sand and Downs.

SANDERLING. A genus of birds of the longirostrous family of Grallæ. They are closely allied to the sandpipers, but have no thumb. The common species, *Calidris arenaria* or *Charadrius calidris*, is somewhat plentiful on the sandy seashores of Great Britain and Ireland. Its length is about 8 inches. In winter, its plumage is a very light ashy grey above, white in front and underneath, and blackish varied with white in the wings; and in summer, the back is spotted with fawn-colour and black, and the breast is dotted with blackish colour. This bird frequents the sea-margin, and feeds on shrimps, sea-worms, and slender crustaceæ.

SAND-LAND. See Sand and Soil.

SAND-MARTIN. See Martin.

SANDPIPER,—scientifically *Tringa*. A genus of birds of the longirostrous family of Grallæ. Their bill is depressed at the end, and commonly not longer than the head; their nasal fossæ are very long; their slightly bordered toes are devoid of membranes at the base; their thumb can scarcely reach the ground; and their whole figure is comparatively short, and their legs moderately long.—The canute or common sandpiper, *Tringa*

grisea, is a well-known inhabitant of the sandy sea-shores of Britain. Its winter plumage is ash-coloured above and white beneath, and has blackish spots on the front of the neck and the breast. Three other species are *Tringa islandica*, with summer plumage, spotted above, fawn-colour and blackish,—*Tringa nævia*, about as large as a snipe, with the coverts of the tail always white striped with black,—and *Tringa maritima*, somewhat smaller than the preceding, with grey upper surface, blackish mantle, whitish belly, and whitishly undulated wings.

SANDSTONE. See FREE-STONE.

SANDWORT,—botanically *Arenaria*. A genus of ornamental plants, of the carnation family. Six species grow wild in Britain; about 70 have been introduced from other countries, principally Continental Europe and Western Asia; and about 90 more are known. A few of the introduced species are hardy annuals, principally with purple or red flowers; and a great majority of the others are hardy, evergreen, herbaceous perennials, almost all white-flowered and between 2 and 8 inches high.

The mediate sandwort, or sea-spurrey sandwort, *Arenaria media*, is an annual weed of the sea-coasts and salt-marshes of Britain. The root is fusiform; many succulent, leafy-stems of 3 inches or so in height, arise from each root; the leaves are convex and smooth; the flowers are minute and of a purple colour, and bloom in July; and the seeds are flat, round, and smooth, and have a membranous border. This plant possesses a considerable resemblance to samphire; and is sold and pickled, in considerable quantities, as a substitute for it.—The vernal sandwort, *A. verna*, is a perennial-rooted evergreen herb of the mountains of Britain, and has a length of about 3 inches, and carries white flowers from May till August.—The fine-leaved sandwort, *A. tenuifolia*, is an annual weed of the sandy fields of some parts of England, and has a height of 5 or 6 inches, and carries white flowers in June and July. Three varieties of it have been introduced from France.—The fascicled or fastigiate sandwort, *A. fasciculata*, is a curious annual weed of the mountains of some parts of Scotland, and has a height of about 6 inches, and carries white flowers in June.—The red sandwort, *A. rubra*, is an annual indigen of sandy fields in both England and Scotland, and is smaller than even the mediate sandwort, and carries purple flowers from June till August.—The larch-leaved sandwort, *A. laricifolia*, is a herbaceous, evergreen perennial of Britain, and has a height of about 3 inches, and carries white flowers in August.

SANGUINARIA. See BLOODWORT.

SANGUISORBA. See GREAT BURNET.

SANICLE,—botanically *Sanicula*. A small genus of hardy, perennial-rooted, herbaceous plants, of the umbelliferous order. The European or wood sanicle, *S. europæa*, is an abundant weed of the groves and woods of Britain. Its root is tufted with fleshy fibres; its stem is from 12 to 24 inches high; its leaves grow for the most part from the root-crown, and are simple, deeply cloven or lobed, and of a dark shining green colour; its umbels are capitate, and form an irregular, twice-compound, umbellate panicle; and its flowers have a creamy white colour, and bloom in June and July. This plant has bitter, acrid, pungent, and somewhat aromatic properties; and it was formerly regarded as a valuable vulnerary; and it thence obtained the name of sanicle, from a Latin word signifying "to heal."

SANSEVIERA. A genus of exotic, evergreen, herbaceous plants, of the day-lily tribe,—The Ceylon species, *S. zeylanica*, was introduced to the hothouses of Britain in the former part of last century. Its root is perennial; its stem is about 2 feet high; and its flowers have a herbaceous colour, and bloom from midsummer till November. The juice of its tender shoots is given in India to young children to clear their throats of viscid phlegm. The root has a warmish taste and a not unpleasant odour, and is made into an electuary by the Indian pharmacists for the cure or alleviation of chronic coughs and pulmonary complaints. The tough stringy fibres are manufactured by the Hindoos into very valuable cordage of various sizes; and the plant is also capable of being made the material of a pretty good paper.—About a dozen other species, all of curious appearance, and most about 2 feet high, have been introduced to British hothouse collections; and a small, ornamental, Chinese species, *S. carnea*, about 6 inches high, and carrying flesh-coloured flowers from March till June, has been introduced to a place on the open flower border.

SANTALUM. See SANDAL-WOOD.

SANTOLINA. See LAVENDER COTTON.

SANVITALIA. A small genus of ornamental plants, of the sunflower-division of the composite order. The procumbent species, *S. procumbens*, is a beautiful, trailing, yellow-flowered, late-blooming, hardy annual; and was introduced to Britain about 50 years ago from Mexico; and will thrive in any common garden soil.

SAP. The liquid which ascends from the spongioles to the leaves of plants, and which contains all the principles of their nourishment, which they derive from or through the soil. See the articles ABSORPTION IN PLANTS, ASCENT OF SAP, CAMBIUM, ALBURNUM, FOOD OF PLANTS, and NUTRITION. The sap in plants is somewhat analogous to the chyme and the chyle in animals; just as the cambium which the sap goes to form performs analogous functions to the blood which the chyme and the chyle go to form; yet the analogy is very far from being complete, and must not be pushed such a length as to confound any of the broad and essential distinctions between vegetable and animal organism. See the article ANALOGY.

Sap, in so far as it has been examined, is in

some instances sweetish, in others slightly saline, and in most insipid. It is liquid and limpid and watery-looking; and consists mainly of water holding a great variety of saline and gaseous substances in solution. It combines in all proportions with water, and, when viscid or thickish, is diluted by it into a thoroughly fluid state. If exposed to strong heat, it emits bubbles of carbonic acid, and exhales a strong odour of vinegar; if submitted to distillation, it yields carbonate of ammonia; and if subjected to chemical agency, it combines readily with alkalies, and suffers thereby a neutralization of all its acid properties. But it has as yet been analysed or even closely examined in the case of but few plants; and it evidently varies widely in composition in different species, and contains principles in some which it wants in others. The sap of *Fagus sylvatica* was found by Vauquelin to contain water, gallic acid, tannin, mucous and extractive matter, acetate of potash, acetate of alumina, and acetate of lime with excess of acid. The sap of the birch and of some other trees can be manufactured into a very pleasant wine; the sap of the sugar maple is well known to yield a large proportion of the sugar used by the population of North America; and the sap of many trees, when thrown out of its course by punctures and fractures, or when enfeebled or vitiated by the want of a due proportion of azotised matter, forms most of the gums and balsams and similar vegetable exudations which are used in medicine and the arts. The sap of almost any tree or shrub may be artificially withdrawn, at any time during the rifest period of its ascent, by cutting asunder a shoot or a young branch, or by boring the stem or a main branch; and it flows chiefly from the tubes of the alburnum,—yet, in some trees, will not come from any shallower bore than one to the centre of the stem. In 24 hours, a branch of a vine has been known to yield from 12 to 16 ounces; and in the course of a season, a birch tree has been known to yield a quantity equal to its own weight, and a maple tree about 28 gallons. The several kinds of morbid and accidental diversions or outpourings of sap from its natural course are noticed in the article Extravasation.

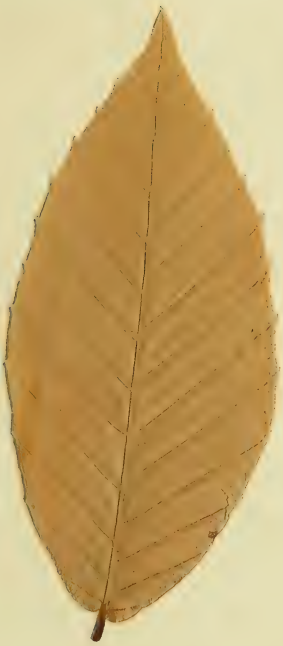
SAPINDUS. See Soap-Berry.

SAPIUM. A genus of ornamental, tropical, ever-green trees, of the spurge family. Four species, varying in natural height from 20 to 35 feet, have been introduced to Britain; and several more are known. The name sapium alludes to an unctuous fatty-looking exudation which flows from any wound in the trunk. Two of the introduced species possess properties somewhat akin to those of the poisonous manchineel. See the article Manchineel.

SAPONARIA. See Soapwort.

SAPOTA,—botanically *Achras Sapota*. An exotic, evergreen, ornamental, economical, corolliflorous tree, constituting the type of the natural order Sapoteæ. It was introduced from South America to the hothouse collections of Britain in the former part of last century. Its natural height is about 35 or 40 feet; its stem is straight, and has ash-coloured bark; its branches are produced on every side, and form a regular head; its leaves are a foot in length, and nearly 3 inches broad in the middle, and taper to a point at each end; its flowers have a cream-colour, and grow on the branches; and its fruit are large and oval or top-shaped, and have a brownish skin, or thick russet-coloured pulp, and are very luscious, and somewhat resemble the marmalade of quinces. The seeds of this plant possess somewhat aperient and diuretic properties; and the juice of it, as also that of some species nearly allied to it, is milky and constitutes a wholesome beverage or article of food. The name sapota is sometimes popularly given to the whole genus. See the article Achras.—The plants of the order Sapoteæ are either trees or shrubs, chiefly evergreen,—most of them tropical, and a few in the warmer parts of the southern temperate zone, but none natives of Europe. "The Sapoteæ," says Loudon, "are chiefly valuable for their fruit, which, in many cases, contributes richly to the dessert. Mimusops-elengi, Imbricaria malabarica, and Argania sideroxylon, are all of this description. The star-apples of the West Indies, the produce of several species of Chrysophyllum, and particularly of C. Caïnito, are esteemed delicious, and the medlars, lucumas, and sapotillas of equinoctial America, all the fruit of different kinds of Achras, are among the most valuable productions of the western world. The seeds of all the order are oily; and their oil is not fluid, but so concrete as to have the appearance and consistence of butter, whence the name of butter-tree has been applied to different species both in Africa and India. The most famous of this description is the Indian mava, mahva, or madhuca, the Bassia butyracea of botanists,—the seeds of which are so oleaginous, that a single tree has been known to produce three quintals of oil. The dried flowers of the same tree are mixed by some Indians with their food, and a kind of spirit is distilled from them by others." Upwards of 30 hothouse species, and upwards of a dozen greenhouse and hardy species have been introduced to Britain. See the articles Bassia, Star-Apple, Iron-Wood, Mimusops, Lucuma, and Bumelia.

SARACHA. A genus of ornamental exotic plants, of the nightshade family. The umbelled and the procumbent species are trailing, summer-blooming annuals, with pale yellow flowers, and with stems of 3 or 4 feet in length, and were introduced to Britain about 26 years ago from Peru. The clammy species, *L. viscosa*, is a deciduous, greenhouse, curious-looking shrub, and carries olive-coloured and white-spotted flowers in autumn, and is also an introduced plant and



a native of Peru. It takes the name "clammy" from its herbage.

SARCANTHUS. A genus of ornamental, tropical, epiphytous plants, of the orchis order. The name signifies "flesh-flower," and alludes to the texture of the sepals. A number of species have been introduced to British orchis-houses from India and China; and three of the most beautiful of these are the spotted, the bitten, and the panicled.

SARCOCAULON. A small genus of ornamental, Cape-of-Good-Hope, evergreen, undershrubs, of the geranium tribe. Two or three purple-flowered, summer-blooming species have been introduced to Britain.

SARCOCEPHALUS. See GUINEA PEACH.

SARCOCOLL. The concrete juice of the African evergreen shrub *Penœa sarcocolla.* It resembles gum arabic in both appearance and properties, but is closely allied to the saccharine matter of liquorice in chemical constitution. It is sweetish, and forms a mucilage with water.

SARRACENIA. A genus of curious, evergreen, herbaceous, North-American, thalamiflorous plants, constituting the natural order Sarraceniaceæ. Six species are known; and all are inhabitants of swamps. They differ from plants of the poppy and the water-lily orders principally in having a broad peltate leafy stigma; and they are sometimes popularly called side-saddle-flowers; but they excite the attention of the curious, and claim a place in garden collections, chiefly on account of the very singular form of their leaves. The earliest-known one may serve as a specimen of the whole; and is described as follows by Miller: —"This hath a strong fibrous root, which strikes deep into the soft earth, from which arise 5, 6, or 7 leaves, in proportion to the strength of the plant; these are about 5 inches long; they are hollow like a pitcher, narrow at their base, but swell out large at the top; their outer sides are rounded, but on their inner sides they are a little compressed, and have a broad leafy border running longitudinally the whole length of the tube; and to the rounded part of the leaf there is on the top a large appendage or ear standing erect, of a brownish colour; this surrounds the outside of the leaves about two-thirds of the top, it is eared at both ends, and waved round the border. From the centre of the root, between the leaves, arises a strong, round, naked footstalk about a foot high, sustaining one nodding flower at the top, which has a double empalement." The sarracenias cannot be very easily managed in gardens; and require frame protection, a bog soil, and constant moisture. They are propagated by division of the root.

SARSAPARILLA. A North-American, climbing, medicinal plant, of the smilax genus and order,—*Smilax sarsaparilla.* The root is perennial, and divides into straight, brown, internally white branches, 3 or 4 feet long, and rather thicker than a goose-quill; the stems are long, slender, shrubby, and spinous; the leaves are alternate, petiolate, ovate, and pointed, and have long tendrils at the base; the flowers grow in groups of 3 or 4 upon one peduncle, and have a herbaceous colour, and bloom in July and August; and the fruit are round three-celled berries, each containing two globular seeds. The root is the part employed in medicine; and has a mucilaginous and slightly bitter taste; and yields its virtues to either cold or hot water by maceration. It possesses demulcent properties; and is possibly of some use in scrofula, elephantiasis, and chronic rheumatisms. But its chief fame was formerly in a very different department of pharmacy, and has now in a main degree passed away. The plant was introduced to Britain in the latter part of the 17th century, and can be cultivated in a soil of sandy peat in the open ground. Three other medicinal species, closely allied to it, the long-leaved, the Chinese, and the syphilitic, have been introduced from respectively North America, China, and Trinidad. The word sarsaparilla or zarzaparilla signifies, in the Spanish language, a bushy little vine, and alludes to the native habit of the plant.

SASSAFRAS,—botanically *Laurus Sassafras.* A medicinal, hardy, deciduous, North American tree, of the laurel genus. It was introduced to Britain in the former part of the 17th century; and is frequently reared in shrubberies as an ornamental plant. Its natural height is from 20 to 50 feet; it stem is about a foot in girth, and has rough, furrowed, grey bark; its leaves are alternate, petiolate, lucid green above, and downy below, and have different shapes and sizes, some being oval, entire, and about 4 inches long, and a greater number lobed and about 6 inches long; its flowers are small, and grow in pendent panicles, and have a herbaceous colour, and bloom in May and June; and its fruit are oval deep-blue berries, each standing on a footstalk of an inch or two in length, and contained in a small red cup. The wood, the root, and the bark are medicinal; and have a fragrant odour and a sweetish aromatic taste; and owe their virtues to an essential oil, which can be separated by distillation. Sassafras is diaphoretic, stimulating, and diuretic; and is used in cases of gout, scurvy, chronic rheumatism, and cutaneous diseases.

SATIN FLOWER. See HONESTY.

SATUREJA. See SAVORY.

SATYRIUM. A genus of ornamental, tuberous-rooted, Cape-of-Good-Hope plants, of the orchis family. Seven or eight species have been introduced to British gardens; and about a dozen more are known. One of the introduced species, *S. carneum*, is peculiarly handsome, attaining a height of about 20 inches, and carrying pink flowers from June till September; and two, *S. papillosum* and *S. candidum*, have the recommendation of emitting from their flowers a fragrance similar to that of *Anthoxanthum odoratum*,

The satyriums are rather difficult of cultivation; but, in general, require greenhouse heat and a soil of sandy peat, and must be judiciously treated in accordance with their periods of growth and repose.

SAURKRAUT. A preserved preparation of cabbages, in common use and great esteem throughout a large part of Germany. The cabbages are cut into thin slices by hand or by a machine similar to a turnip slicer. A thick sprinkling of salt is shed on the bottom of a cask; a layer of cabbage, 6 inches thick, and seasoned or intersprinkled with whole pepper and juniper berries, is placed on the salt; alternations of the salt and the cabbage are continued till the cask is filled; a circular board, with a heavy weight on it, is placed on the topmost layer; and, when the mess ferments and sinks, additional alternations of salt and cabbage are put in till the vacuum is filled; and, afterwards from time to time, the old juice is poured off and a solution of salt poured in instead of it, till scum and fetor entirely cease. The saurkraut is now made, and may either be kept in store or be immediately begun to be used; and, whenever a portion of it is taken out, a sufficient quantity of brine must be left to cover all which remains, and to exclude the air; and the cask must ever be kept as closely as possible covered with a cloth and with the circular board and the weight. Saurkraut, when washed in fresh water, and stewed with bacon or with salted meat, is much relished by persons who have used it from their youth, and acts as a preventive of sea-scurvy in long voyages.

SAUROGLOSSUM. See Lizard's Tongue.

SAURURUS. See Lizard's Tail.

SAUSSUREA. A genus of hardy, perennial-rooted, herbaceous plants, of the thistle division of the composite order. The alpine saussurea or alpine saw-wort, *S. alpina*—called by Linnæus *Serratula alpina*—is an inhabitant of the fissures of rocks on the mountains of Britain. Its stem is from 3 to 12 inches high; its leaves are simple, distantly toothed, and cottony and very white on the under surface,—and the lower ones stand on longish channelled footstalks; and its flowers are few, and grow in a corymbose tuft, and have pink florets and blue anthers, and bloom in July and August, and make a very beautiful appearance. Ten species, chiefly with purple or red flowers, and all more or less ornamental, have been introduced from Caucasus, Siberia, and Continental Europe.

SAVINE,—botanically *Juniperus Sabina*. A medicinal and ornamental, hardy, evergreen shrub, of the juniper genus. It is a native of the South of Europe and of the Levant, and was introduced to Britain about the middle of the 16th century. Its ordinary height is 3 or 4 feet; its bark is brown; its leaves are numerous, and completely clothed with foliage; its leaves are opposite, pointed, firm, erect, and very small, and lie over one another, and give the whole plant a very lively appearance; the male catkins consist each of three times three flowers in rows, and of a tenth flower at the end; and the fruit are blackish-purple, fleshy, tuberculated, berry-like cones, each containing three small hard seeds. The leaves and tops are the parts used in medicine; and have a hot, bitter, acrid taste, and a strong, heavy, unpleasant odour; and owe their virtues to an essential oil, which can be separated by distillation. Savine is anthelmintic, emmenagogic, diaphoretic, and powerfully stimulating; and is used, in the form of ointment or of lotion, for scabies and gangrenous sores,—in the form of externally applied dried powder, for warts, carious bones, and flabby ulcers,—and in the form of internally administered powder, for gout and for certain diseases of the uterine system,—but requires to be used in the last of these ways, with great skill and caution.

SAVORY,—botanically *Satureja*. A diversified genus of plants, of the labiate order. About 15 species have been introduced to Britain from the islands and sea-boards of the Mediterranean, from the western African islands, from Carniola, and from Jamaica; and some of these are culinary, some ornamental, and some uninteresting,—one is an annual, some are herbaceous evergreens, and most are evergreen undershrubs. We need particularly notice only the two most common culinary species.

The summer or garden savory, *Satureja hortensis*, is a native of Italy and of the south of France, and was introduced to Britain about the middle of the 17th century. It is an annual, and rises with slender erect stems about a foot high, sending out branches at each joint by pairs, garnished with leaves placed by pairs, about an inch long, and one eighth of an inch broad,—stiff, a little hairy, and emitting an aromatic odour when rubbed. The flowers grow from the wings of the leaves toward the upper part of the branches, each footstalk sustaining two; the upper lip is erect and indented at the point, and the lower is divided into 3 almost equal parts; the flowers have a pale flesh colour, and bloom in July; and the seeds ripen in autumn. This plant possesses aromatic properties, and is used in the kitchen for flavouring. It may be raised from seeds sown in March, either in drills 6 or 9 inches apart, or broadcast, raked in and either thinned out to distances of 9 inches, or transplanted in June.

The winter or mountain savory, *Satureja montana*, is a native of the same countries as the summer savory, and was introduced to Britain about the middle of the 16th century. Its root is perennial; its stem is low, branching, and shrubby; its branches are ligneous, and rise about a foot high, and are garnished at each joint, with two very narrow leaves about an inch long, and send out from their base a few small leaves in clusters; and its flowers grow on short footstalks from the wings of the leaves, and are

larger and paler than those of the summer savory, and bloom in June and July. This plant is used for the same purposes as the summer savory, and has also some small medicinal reputation as an aromatic. It thrives best on poor dry soil, and may be propagated from slips or cuttings, planted in April or June, on a shady border, and the young plants must be transplanted to distances of 12 inches, and the grown plants kept bushy by cutting. One planting will serve for several years.

SAVOY, or SAVOY-CABBAGE,—botanically *Brassica Oleracea Bullata Major*. A well-known variety of the common cabbage. See the article CABBAGE. It is distinguished from the common bolling cabbages, or the varieties of *B. o. capitata*, principally by the puckering of its leaves. It is one of the prime winter vegetables, and well merits the attention of every person who has a kitchen garden, whether large or small. It comprises three subvarieties,—the large yellow, the green, and the smaller green; and the last of these is the hardiest.

The savoy must be sown early in spring, and treated similarly in the seed-bed to other spring-sown cabbages. In England, the transplanting of it, for the main winter supply, is commonly done at two or three periods in July; but in Scotland, this work should be commenced at an earlier period, and completed by the middle of that month. The soil for savoys should be rich in quality and rather light in texture, and ought to be well digged and pulverized. "Draw drills or shallow trenches about 30 inches apart; tread along the drills or press them with a broad pole, till the soil become smooth and compact; then plant the savoys 18 inches asunder, filling the holes with water and fixing the roots firmly in the soil. After they have become established, and begun to grow, the spaces will require the hoeings and diggings which are so essential to the progress of plants of all the cabbage family. As winter approaches, the earth ought to be brought up to and about the stems. If the planting be done in open, manured trenches, in dry weather, it will not only secure the growth of the plants, but greatly tend to protect them from frosts during winter. Savoys are not considered to be in perfection, till they have been exposed to a degree of frost; but they will ever after be fit for the table throughout the winter months."

SAW-DUST. Any kind of saw-dust may be very profitably converted to manuring purposes, either by using it for litter, and setting it up to ferment in mixture with about an equal quantity of common farm-yard manure, or by making a compost of it with about one-tenth of its bulk of lime, and with additions of road-scrapings and any similar substances, and allowing the compost heap to stand about three years before being used. Both of these preparations of saw-dust have been found, by actual trial, to be very good manure for turnips; and wherever saw-dust is employed in composts in any greater preponderance than we have indicated, or even in the mere degree which we have indicated, it might probably receive powerful aid from a top-dressing of nitrate of soda. A coating or thick sprinkling of fresh oak saw-dust on gravel walks, effectually prevents the growth of weeds.

SAW-FLIES. A large and mischievous family of hymenopterous insects. It possesses a deep interest to foresters, gardeners, and farmers, on account of the ravages which its larvæ make upon their crops,—particularly upon amentaceous trees, the most common fruit shrubs, and all sorts of turnips. The type of the family is the genus Tenthredo; and the scientific name of the whole, is therefore Tenthredinetæ.

The saw-flies are easily recognised by the continuousness of their abdomen with their thorax,—by the ragged appearance of their wings,—by two little rounded, granular, and usually coloured bodies situated behind the scutellum,—and by their sluggish disposition and heavy port. Their abdomen is cylindrical throughout its length, and rounded posteriorly, and comprises nine annuli, and is so closely and completely joined to the thorax as to look to be continuous with it; their antennæ differ, as to both form and composition, in different species; their mandibles are elongated, compressed, strong, and dentated; their palpi comprise six joints, and are filiform or nearly setaceous; their ligula is straight, rounded, and divided into three double portions, the intermediate of which is the narrowest; their wings are always divided into numerous cells; and their ovipositor, or egg-depositing instrument possessed by the females, is double, moveable, squamous, serrated, and pointed, and lies within a case or sheath of two concave laminæ, and is the particular object referred to in the name saw-flies. "This instrument has been variously described by authors, according to the view they have respectively taken of it, and the different species in which they happened to examine it; but it consists essentially of two pieces moving upon each other, which are smooth on their internal sides, but serrated externally with sharp oblique striæ and elevated lines; these parts being strengthened and supported by a kind of sheath composed of several pieces. When this instrument is made to act on the surface of a leaf, or a tender shoot, the lateral teeth act as a saw, while the ridges at the same time perform the office of a file or rasp. Some of the flies make a simple series of slits, others two series close together, a single egg being placed in each. Sometimes the incisions are made along the outer edge of a leaf, at others along the longitudinal ribs, and in some instances, the eggs are merely attached by a gummy substance to the surface. Not only does the saw make the necessary openings, but it irritates the wound to such a degree as to cause an overflowing of the sap; and this sap, in certain instances, is im-

bibed in some unknown manner through the membranous skin of the egg, which in this anomalous way is nourished and enlarged. In other instances the extravasated juices produce galls, which afford at once food and lodging to the young larvæ."

The larvæ of saw-flies are often called false caterpillars or pseudo-caterpillars, in consequence of their possessing a general resemblance to the larvæ of moths and butterflies, in at once the form of their body, its colours, the exterior dispositions of its dermis, and the great number of their feet; and they are the more liable to be mistaken for true caterpillars, that the two classes of depredators are often at work together in ravaging the same plant. The segments of their body generally amount to twelve; but the incisures are indistinct, and are liable to be confounded with the transverse wrinkles which abound upon the whole surface. Most of the larvæ have only one colour; yet many are marked with bright and varied colours; and so great a change of colour often takes place at moulting, an old colour being succeeded by a totally different one, that it is impossible for a general observer to recognise the same individual. Such species, too, as are furnished with tubercles or spines in the earlier stages of their larva existence, lose them at their last moult, and become smooth. All the larvæ, like the saw-flies themselves, are sluggish and comparatively inactive, seldom moving from the places of their original or periodical fixture, except when they require a new source or additional supply of food. Some lodge in the interior of fruits, and cause them speedily to decay; and some live in the interior of tender shoots, and feed on the immature pith; but the greater number live exposed on the foliage of plants,—and when not engaged in feeding, or when apprehensive of danger, most of them roll themselves into a circle, sometimes with the tail elevated in the centre. "It is of great importance to be able to distinguish the larvæ of saw-flies from the caterpillars of moths and butterflies, as the preventive or remedial treatment required for the one is often very different from what it might be desirable to adopt in regard to the other; and this distinction is easily made. True caterpillars, that is, the larvæ of butterflies and moths, have never more than 16 feet; while the larvæ of saw-flies, or false caterpillars, have generally from 18 to 22; a few have only 6, a circumstance which again distinguishes them from true caterpillars, in which the number of these parts is never below 10. Another mark of distinction is afforded by the structure of the abdominal feet. The pectoral ones are always nearly alike in both. In lepidopterous larvæ, the former are surmounted by a cornet of small hooks, which are never found in those of false caterpillars, as their abdominal legs are simple membranous protuberances. This difference of structure occasions a difference in habit, which may often enable us to determine at first sight to which of the two orders in question a caterpillar belongs, when it is seen even at a distance feeding on a leaf. The true caterpillar clings to the leaf by its abdominal legs, while the head is left free, and often borne elevated, the pectoral legs being used merely as points of support. In false caterpillars, exactly the reverse of this takes place. The pectoral legs embrace the leaf, so that the head is kept close to it; while the abdomen, unprovided with prehensory appendages, is left quite free, and is generally borne upwards, and not unfrequently twisted into various singular postures, sometimes curved inwards, at other times arched, and occasionally assuming the form of the letter S."

The pine saw-fly, called *Lophyrus* by Latreille, comprises three known British species, which sometimes work serious havoc upon pine and fir plantations. The antennæ of all the species comprise about 22 joints in the male, and from 16 to 18 in the female, and are bipectinated in the former and simply serrated internally in the latter; the mandibles are strong,—the one unidentate, and the other tridentate near the top; the maxillary palpæ are long and six-jointed; and the ocelli are three, and placed nearly in a straight line. The larvæ of all the three species—severally called *L. pini*, *L. rufus*, and *L. pallidus*—prey on the Scotch pine; but, like all others of the family, they considerably change their appearance and their colours at successive periods of their growth, and may, for all practical purposes, be recognised far more readily by their habits and their general structure than by their specific characters. "These caterpillars," says Mr. Duncan, in reference to those of *L. pini*, "attain a large size when compared with the perfect insect. Their voracity is very great; they seem, in fact, to eat with scarcely any intermission. They assemble in family parties consisting of from 50 to upwards of 100 individuals, and appear to take pleasure in carrying on all their operations in company. They place themselves along the leaves, and commencing at the top eat downwards to the sheath; very young larvæ leave the midrib standing. When the branch is suddenly struck, or they are otherwise disturbed, they quickly raise the head and anterior part of the body, and emit a drop of fluid from the mouth; and it is curious to observe a large number doing this simultaneously, and many times in succession, if the annoyance be repeated. The fluid discharged has nearly the same smell and consistency as the resinous juice of the trees on which they feed. The moultings take place exactly in the same way as in other caterpillars, and the exuviæ are observed in great quantities adhering to the branches which they have passed over." "Many of these caterpillars," he continues, in reference to those of all the three species, "fall a sacrifice to the attacks of ichneu-

mons; and when the caterpillars are young, or immediately after changing their skin, they are destroyed in great numbers by continued cold and wet weather, or hoar frost during the night. Among their other natural enemies may also be mentioned insectivorous birds, particularly the tribe of woodpeckers, which, however, are too scarce in our Scottish woods to be of much service. Mice and squirrels feed upon the pupæ, and in some cases have been known to destroy great numbers of them. After having been made acquainted with the appearance of the flies, boys might be employed with much advantage to catch them when they first begin to appear, using for this purpose a small bag-net made of gauze. The flies are at no time very active, and when employed in oviposition, they are so engrossed with their occupation, that they may be approached and secured without much difficulty. When the caterpillars abound on a branch, many of them may be brought to the ground by suddenly shaking it, or, what would be still more effectual, striking it smartly with a pole; they can then be destroyed by trampling upon them, or if a large sheet be previously spread beneath the tree, collected and otherwise disposed of. The best time for doing this is early in the morning after a cold night, as the caterpillars are then somewhat stiff and inactive, and therefore much more easily displaced. When they have prevailed for a time, and numbers have disappeared, it may be presumed that they have entered upon the pupa state; and if the moss and withered foliage be collected from the stems and roots of the trees and burnt, many will thus be destroyed. It is important also to examine the crevices of the bark, where many take up their abode; and Kollar recommends that the stem should be covered with sand a foot and a half high, and as broad, on the ground; as the larvæ and pupæ thus will not easily escape from the chinks, particularly in old trunks, where the bark is very hard, but must be stifled in the sand, and those saw-flies that are developed cannot make their way out of the sand into the open air."

The pear-tree saw-fly, *Selandria æthiops*, called by Linnæus *Tenthredo cerasi*, produces the well-known slimy grub of the pear-tree and the fruit trees. The fly is about 2½ lines long; and has short nine-jointed antennæ, with simple terminal joints,—a short, broad, black, and shining body,—and thin and somewhat hyaline wings with black nervures, and with two marginal and four submarginal cells. The larva is always covered with a kind of viscid slime; and has a dark greenish black colour; and often inflates its body and varies its shape; and resembles frequently a small snail, and sometimes a tadpole. It is an almost annual assailant of the foliage of orchards, and so riddles and skeletonizes the leaves which it attacks as to make them appear at a little distance as if they had been scorched by lightning. It makes repeated moultings among the foliage, and leaves its exuviæ in a collapsed and contracted state resembling a black thread. Some of the methods used for destroying caterpillars may be advantageously employed against it; and a sprinkling of quicklime, also, would adhere closely to its slime, and perhaps ultimately kill the larvæ.

The saw-flies of the genus *Nematus* comprise nearly forty British species, and attack a wide variety of our useful plants. Their antennæ are nine-jointed, and have the first and the second joints short and the third rather longish; their ocelli are three, and form a small triangle on the crown of the head; their mandibles are strong and acute, and usually have a single tooth on the inner edge; their wings have one marginal and four submarginal cells; and all the joints of their tarsi are of nearly equal thickness throughout their whole length. The larva of one species feeds upon the poplar; that of another lives in society on the willow; and that of another commits extensive ravages upon osier plantations. But by far the most destructive is the larva of *Nematus grossulariæ*, which feeds on the gooseberry plant, and whose habits and treatment may be regarded as sufficiently illustrating those of all the rest. The fly of this species or gooseberry saw-fly is from 4 to 5 lines long; its head is black; the organs of its mouth are more or less yellowish; its antennæ are black above and pale yellow below; its thorax is yellow, but with the disk more or less marked with black; its abdomen and its legs are yellow; and its tarsi, and sometimes the tips of the two posterior tibiæ, are black. The eggs are deposited on the under-surface of the leaves of the gooseberry plant in necklace-like rows along the principal nervures; and, in fine weather, are hatched in 7 or 8 days. The larva, when full-grown, is about three-fourths of an inch long; but usually appears less in consequence of carrying its tail curved inwards. Its head is black; its body is glaucous or bluish-green, mingled with yellow; and each segment is marked with several transverse rows of black shining piliferous warts. It makes several moultings, leaves its exuviæ on the leaves or twigs, and continues altogether as a larva during from 14 to 17 days. The pupa is longer in arriving at maturity than the larva; and, when it comes into existence late in the season, it continues throughout the winter. Two generations of larvæ almost always occur in the year,—the one in the beginning of summer, and the other toward its close; and often occasional and comparatively small broods also appear throughout the intervening period. The larvæ live in associations of from about 50 to upwards of 1,000 upon a bush; and they consume all the soft portions of the foliage, leaving only the footstalks and the principal ribs of the leaves. Various methods of destroying the larvæ or of preventing their appearance have been recommended. Attacks upon

the fly itself are of trivial efficiency; the leaves which have rows of eggs upon them may be advantageously hand-picked; and all attacks upon the larvæ themselves ought to be made as soon as possible after they appear. Gentle blows may be given to the bush to shake them down; quicklime may be cautiously sprinkled in sufficient quantity to make them drop; a wash of lime-water may be applied cold; a liquid preparation or decotion of soft soap and a little tobacco may be squirted on lukewarm; or hot water, of the temperature of from 120° to 140° Fahrenheit, may be forcibly thrown with a watering-pot or a forcing-pump. If attempts be postponed till the period of the pupa-state of the insect, they must be directed entirely to the soil around the infested bushes; and may consist in a drenching with cattle urine, or in a thick coating of seawrack, or in the depositing of a layer of unslaked lime about an inch or so beneath the surface, in such a way that all the heat evolved during the process of natural slaking will be confined within the region occupied by the pupæ.

The turnip saw-fly, *Athalia spinarum*, belongs to a genus which comprises 5 or 6 other British species, and requires to be rather minutely known in order to be distinguishable from these. The genus *Athalia* has short and somewhat club-shaped antennæ, nine or ten jointed in the male, apparently eleven-jointed in the female, the third one as long or longer than any other two,—long six-jointed maxillary palpi, the radical joint shortest,—four-jointed labial palpi, the joints nearly of equal length,—thick-based mandibles, terminating in a curved claw with a tooth,—two-lobed maxillæ, with the one lobe ovate-ended, and the other long and pointed,—and superior wings with two marginal and four submarginal cells. The species *Athalia spinarum* is from 3 to 3½ lines long, exclusive of the antennæ; and has been described as follows:—"Head wider than long, deep black, with three ocelli in the centre; eyes oval; antennæ black above, and for the most part dull yellow beneath; labrum and palpi light yellow; thorax black above, with a triangular space in front, the scutellum and a spot behind it reddish-orange; the collar, which is rather long and slender, black on the sides and yellow in the middle; abdomen rather short, entirely orange-yellow, inclining to red, with a small black spot on each side of the first segment; legs likewise orange-yellow, the tarsi paler, approaching to whitish, the tip of the tibiæ and of each of the tarsal joints black; the tibiæ with two spines at the apex, and the joints of the tarsus each with a very slender lobe beneath; extremity of the ovipositor black; wings yellowish at the base, the costa and stigma black." But several slight varieties occur; and in particular, the thorax is sometimes entirely black, and the scutellum is often of the same colour. The eggs are deposited on the young turnip-plants, for the most part round the outer margin of the leaf, in the early part of summer; and, if the weather be favourable, are very soon hatched. The larvæ are at first small, but grow rapidly, and in the course of a few weeks attain their full size. They have at first a deep black colour; but, after their last moult, they have a dark lead or slate grey colour. They are known by a number of popular names, which allude to either their colour or their ravages, such as blacks, black caterpillar, nigger, canker, &c. They attack the turnip-plants as soon as they are hatched, and eat voraciously, and sometimes destroy the whole crop, and seldom do less injury than to occasion dwarfishness in a large proportion of the bulbs; and, when they are touched, or in any way disturbed, they coil themselves up, and remain motionless; and, when full grown, they cease to eat, and either bury themselves in the soil or take refuge among moss, rotten leaves, or other rubbish, there to undergo their transformation into pupæ. The havoc done by these devastators in 1835 and some subsequent years was so great as materially to affect the interests of British agriculture; and the rapidity of it was sometimes such as to astonish and bewilder farmers, who were not acquainted with the saw-fly's habits. A distinct warning is given to ordinarily observant cultivators by the appearance of the flies themselves about a fortnight before the ravages of the larvæ can commence; and the sad retribution awaits any farm where the larvæ appear and are not destructively dealt with, that, after passing into the pupæ state, they give origin in about 20 days, to a fresh race of flies, whose larvæ will destroy a re-sown or second turnip crop. Yet though many preventive and remedial means have been tried, really effective ones are either not uniform or comparatively critical, dear, or difficult.

The destruction of the turnip saw-flies themselves is a prime remedy, in so much that the killing of every individual fly is the prevention of an entire colony or succession of colonies of larvæ. The flies are so sluggish and inactive, and so seldom fly speedily or to a distance, that they can easily be caught by means of a small bag-net or even by the hand. A distinguished farmer in Yorkshire states, in the Highland Society's Transactions, that he always instructs his turnip-hoers to leave their work and chase and destroy every saw-fly they see, and that, simply in consequence, as he believes, of this one precaution, his turnip-fields have escaped injury while others in the same parish were more or less consumed. Swallows eat the flies, and sometimes skim over the fields in search of them, and then do valuable service; and rooks also make such sweeping attacks upon the caterpillars, that they have been known to act as complete conservators of a turnip crop in the vicinity of a rookery. Applications of wood-ashes, coal-ashes, quicklime, unslaked lime, soot, saline mixtures, saline solutions, preparations of arsenic, and other sub-

stances have been made by way of sprinkling or aspersion on the crops after the larvæ appeared; but they have been only sometimes or limitedly effectual,—and have, at other times, been either quite useless or positively hurtful. A copious aspersion with sea-water, or a dusting of finely powdered salt at a time when the plants are wet with rain or with heavy dew, is probably the best, as it is the simplest, of these applications. The mere negative remedy of not hoeing or not thinning when the larvæ appear is highly beneficial; for if the crop be allowed to continue thick till the larvæ period cease, more food may be present than the larvæ can consume, and only the sound or the least injured plants may be allowed to stand at the subsequent thinning,—and if the soil be comparatively skinned and hard when the larvæ fall, it will resist their efforts to burrow in it for transformation, and may cause them to perish on the surface. Drawing a cart-rope over the crop to shake off the larvæ is sometimes very effective, but cannot always be depended on. The brushing of the drills with live twigs, either vibratingly twice or thrice a-day during the whole larvæ period so as to dislodge the larvæ from their feeding-hold of the plants, or switchingly a single time or two times so as to sweep the larvæ aside into the spaces between the drills, has also been found effectual; and in the latter case, the persons brushing must crush the larvæ with their feet as they pass on, and a man must closely follow with a scuffler to cover the whole spaces between the drills. By far the best method, however, is either hand-picking or the use of poultry, particularly young ducks. "Hand-picking, it is true, is tedious, if not expensive, where the caterpillars are so numerous that as many as 16 score have been counted on one large plant; but in such cases they should be brushed or whipped off into fruit-baskets or sieves; otherwise pint or smaller pots are well adapted for collecting them, which can be emptied into large covered vessels at the head of the field, containing some salt and water, or lime-water, to prevent the caterpillars from crawling out." Even in fields where the larvæ are by no means abundant, five or six children, of from 6 to 10 years of age, gathering only 8 hours a-day, will collect in a week about 45,000 or 50,000. As to poultry, they make sure and clean work; and young ducks, especially, have been tried with universal success, and are now the general favourites,—and they possess at the same time the useful propensity of eating up slugs and other small mischief-working animals. Even when a field has, to some extent, been all but destroyed, the introduction of ducks has speedily changed its appearance. Yet the larvæ ought never to be allowed to make any progress in devastation; and the farmer should be on the watch for them the instant they are hatched, and immediately set his ducks and poultry to do their duty. "Nearly 400 ducks were at work at one time, on two farms in Norfolk, and saved all the crops entrusted to their care. When such large numbers are employed, they ought to be formed into detachments of not more than 100, and each must be attended by a boy or girl, to precede them with a long light pole or willow rod, to brush the caterpillars off the leaves, as well as to drive the birds to water and to rest 3 or 4 times a-day. After drinking, the ducks will often disgorge the caterpillars in great quantities, and soon go to work again with whetted appetites. They must also be driven home at night, and put into a barn, where they ought to be fed with a little barley or other grain to keep them in health and vigour, otherwise so much living animal food disagrees with them, and causes purging. Old ducks do not work well, and are liable to attack the turnip-tops, and do as much harm as good; so that only young ducks should be selected of from 3 to 5 weeks old. Mr. Sells recommends that, after ducks and fowls had been made to fast a few hours, they should be tried with the larvæ, either alone or mixed with barley, by which means they would become acquainted with the insect to be sought for, and probably take a predilection for it."

The corn saw-fly, *Cephus pygmæus*, belongs not properly to the tribe Tenthredinetæ, but forms a connecting link between it and the nearly allied tribe Siricidæ; and it is commonly assigned to the latter tribe, and was called by Linnæus *Sirex pygmæus*. It abounds in Britain, and sometimes inflicts material injury upon wheat and rye crops; and yet it has hitherto been exceedingly little noticed in connexion with agricultural science. The fly has a shining black colour; the head is rather large, and has prominent eyes, and three minute ocelli on the crown; the antennæ have 21 joints, and are tolerably long and slender, but slightly clavate; the thorax is oval and not broader than the head; the abdomen is rather long, slender, and slightly compressed, but has more of the two first of these characters in the male than in the female; and the four wings are transparent and iridescent,—the superior ones with two marginal and four submarginal cells, the costa and stigma yellowish-brown, and all the nervures brown and slender. The larva is 6 lines long, a little thickened anteriorly, nearly cylindrical, of a yellowish milky white colour, tolerably fleshy, and more like a large maggot than a caterpillar; its head is rounded, corneous, and ferruginous, and has minute four-jointed antennæ; its three thoracic segments have each two nipples beneath in place of feet; and its last segment is terminated by a small tubular appendage, which is protrudible like a telescope, and assists the animal in its progress within the interior of a culm. The pupa is enclosed in a transparent cylindrical cocoon, about 5 lines long, rounded at the one end, and irregularly stopped up at the other.

The corn saw-fly may be seen every year in

June on flowers in corn-fields, and on grass in woods; and the larvæ may be found after harvest, and even during winter, ensconced in the stumps or roots of stubble. The flies of a season issue from the cocoons toward the end of May; the females, after the pairing-time, pierce the culms of growing rye or wheat below the first joint, and deposit their eggs in the interior; the eggs are soon hatched within the protection and concentrated heat of their snug position; the young larvæ live on the tender cellular matter of the culms, and on the nutritive juices of the sap, which ought to form the grains in the ear; and, when they become older, they penetrate through the knots to feed in the higher divisions of the culms; and, when they attain full size, they descend to the base, and cut down the straw nearly level with the ground, and descend into the stump a little below the soil, there to remain ensconced for eight months, and to undergo their transformations towards the next year's race of flies. The plants infested with the larvæ never acquire a tolerably full ear of grain,—and become erect and whitened at the top while their healthy neighbours are still green and nodding,—and are liable to be broken off at the foot and thrown completely over by the first considerable wind which blows after they are sawed,—and, when they are pretty numerous and in lines, they make blank and unproductive tracts in a crop of the same appearance as if the field had been traversed in every direction by sportsmen or by quadrupeds. The best means hitherto suggested for preventing these devastations, in any field where the larvæ are known to exist, is either to set fire to the stubble after harvest, or to plough it completely over in March or the beginning of April.

SAW-WORT, botanically *Serratula*. A genus of ornamental herbaceous plants, of the thistle division of the composite order. The name alludes to the sawed form of the leaves. One species grows wild in Britain; about 30—all hardy and chiefly perennial-rooted and purple-flowered —have been introduced to Britain from other countries; and about 10 or 12 more are known.

The common or dyeing saw-wort, *Serratula tinctoria*, inhabits the groves, woods, thickets, and grassy pastures of Britain. Its root is perennial and woody; its stems are annual, erect, straight, solid, angular, striated, reddish, and about 3 feet high; its leaves are pinnatifid, and somewhat lyrate, and have abundant, fine, bristly serratures; its flowers are corymbose, and of a purplish crimson colour, and bloom from July till October; and its seeds have a bristly, yellowish, unequal coronal. This herb gives a yellow colour to wool; and is much used for that purpose in Sweden; and possesses, in some places, the rank of a cultivated plant.

SAXIFRAGE, — botanically *Saxifraga*. A large genus of calyciflorous, ornamental, herbaceous plants, constituting the type of the natural order Saxifrageæ. The plants of this order are principally low-growing herbs, inhabiting mountains, rocky grounds, dry walls, the sides of springs, and peculiar marshy situations, either in the cold regions of the world or in the alpine portions of the hot ones; and they form the most attractive and beautiful of all the groups of alpine flora. They do not possess either grandeur or brilliance or showiness; but as a group, they are eminently distinguished for neatness and perpetuity of low-growing foliage, and for exquisite simplicity and meek, sweet, blushing beauty of blossom. One genus, indeed, is shrubby and quite unlike the rest; but the other genera afford an absolute profusion of the loveliest of the class of ornamental plants which are fittest for clothing rock-work and for decorating the slopes and breaks of naked banks. Five or six greenhouse species, 6 or 7 hardy ligneous species, and nearly 150 hardy herbaceous species occur at present in the wilds and gardens of Britain; and are distributed among 10 genera, —by far the most important of which is Saxifraga itself. A few of the species possess astringent properties; and one, *Heuchera americana*, is said to be lithontriptic and anticancerous.

The saxifrage genus consists chiefly of low, hardy, evergreen herbs, and is, in a sense, somewhat simple and uniform; and yet it has occasioned great perplexity to botanists, and comprises a remarkably rich and almost startling diversity in the aggregate appearance of its plants, and especially in the characters of their foliage. Thirty-two species of it grow wild in Great Britain and Ireland; about 70 species have been introduced from other countries; and about 40 more species are known. The foliage of the genus varies from a cabbagy appearance to a mossy one, and from a smooth to a hairy or a glutinous, and from neat or ordinary to intricate or grotesque; its flower-stalks vary in height from one or two to about 30 inches, and are in some instances slender and naked, in others stout and leafy; its inflorescence is in a few cases solitary, and in the rest either panicled or corymbose; and its flowers are either white, or yellow, or flesh-coloured, or purple, or of some kindred tint, and are often spotted and always meekly and gently beautiful. Most of the species thrive excellently in sandy loam or in any common garden soil; and all the perennials may be readily propagated by radical division, and the few annual ones from seed.

The shady saxifrage, or London pride, or none-so-pretty, *S. umbrosa*, is the best known of all the species, whether indigenous or exotic, and may be advantageously selected as a specimen of the whole. It grows wild on some mountains of Britain; and abounds on the mountains of the south-west and north-west of Ireland; and has a place in the little flower-plots of the humblest cottages; and may sometimes be seen as an ornamental edging-plant in the most aristocratic and

gorgeous flower-gardens. It is an evergreen, and blooms from April till June. "The roots are perennial. The leaves are oblong, oval, and placed circularly at bottom; they have broad, flat, furrowed footstalks near 2 inches long; they are deeply crenated on their edges, which are white. The stalk rises about a foot high, is of a purple colour, stiff, slender, and hairy; it sends out from the side on the upper part several short footstalks terminated by white flowers spotted with red. The stamina are longer than the petals of the flower, as are also the two styles,—and these have red stigmas."

The following species grow wild in both England and Scotland,—The intermediate, *S. media*, on mountains, purple-flowered, a foot high, and blooming from April till June; the toothed, *S. dentata*, on mountains, white-flowered, a foot high, and blooming in May and June; the starry, *S. stellaris*, on the banks of mountain rivulets, white-flowered, 3 or 4 inches high, and blooming in June and July; the grain-rooted, *S. granulata*, on meadows and pastures, white-flowered, a foot high, and blooming in May; the aizoon-like, *S. aizoides*, on the banks of mountain rivulets, yellow-flowered, 5 or 6 inches high, and blooming in July and August; the autumnal, *S. autumnalis*, similar in height and colour of flower and time of blooming to the preceding; the opposite-leaved, *S. oppositifolia*, on mountainous rocky ground, purple-flowered, 1 or 2 inches high, and blooming in March and April; the five-cleft, *S. quinquefida*, on mountains, white-flowered, 6 inches high, and blooming in May and June; the three-fingered, *S. tridactylites*, on walls, white-flowered, 3 or 4 inches high, and blooming in April and May; and the moss-like, *S. hypnoides*, on dry rocks, white-flowered, 3 or 4 inches high, and blooming from April till June. All these species are fibrous-rooted evergreen herbs, except the three-fingered and the grain-rooted, the former of which is an annual, and the latter a tuberous-rooted perennial.

The following species grow wild in England or Wales, but not in Scotland,—The hirculus saxifrage, *S. hirculus*, in turf-bogs, yellow-flowered, 6 inches high, and blooming in August; the deceptive, *S. decipiens*, in moist places, white-flowered, 3 or 4 inches high, and blooming in May and June; the fine-leaved, *S. leptophylla*, on the Welsh mountains, white-flowered, 6 inches high, and blooming in May and June; and the turfy, *S. cæspitosa*, on very lofty Welsh mountains, crimson-flowered, 3 or 4 inches high, and blooming in May and June. The first of these four species is an annual-stemmed perennial, and the other three are fibrous-rooted herbaceous evergreens.

The following grow wild in Scotland, but not in England or in Wales,—The snowy, *S. nivalis*, on lofty Highland mountains, white-flowered, 3 or 4 inches high, and blooming in June and July; the dissimilar, *S. dissimilis*, on the banks of the rivulets of Ben-Nevis, white-flowered, 5 or 6 inches high, and blooming in June and July; the drooping, *S. cernua*, on lofty Highland mountains, white-flowered, 3 or 4 inches high, and blooming in July; the brook, *S. rivularis*, on Highland mountains, white-flowered, 1 or 2 inches high, and blooming in June and July; the pedatifid, *S. pedatifida*, on Highland mountains, white-flowered, 6 inches high, and blooming in May and June; the dwarfish or the musky, *S. pygmæa*, on Highland mountains, white and yellow flowered, 1 or 2 inches high, and blooming in May and June; the stripped, *S. denudata*, on lofty ground, white-flowered, 3 or 4 inches high, and blooming in May and June; the broad-petaled, *S. platypetala*, on rocky mountainous ground, white-flowered, a foot high, and blooming in June; the hairy, *S. hirta*, on lofty Highland mountains, white-flowered, a foot high, and blooming in June; the longish-stalked, *S. elongella*, on Highland mountains, white-flowered, a foot high, and blooming in April and May; the lively-green, *S. lætevirens*, on lofty ground, white-flowered, 6 inches high, and blooming in May and June; the dense, *S. condensata*, on mountains, white-flowered, 3 or 4 inches high, and blooming in May and June; and the pretty, the mossy, the clammy, and the narrow-leaved varieties of *S. hypnoides*, on mountains, white-flowered, 6 inches high, and blooming in May and June. All these peculiarly Scotch kinds are herbaceous evergreens.

The following species grow wild in Ireland, but not in Britain,—The incurved-leaved, *S. incurvifolia*, on rocks, white-flowered, 3 or 4 inches high, and blooming in May and June; the polished, *S. polita*, on mountains, white-flowered, a foot high, and blooming in May and June; the geum, *S. geum*, on mountains, white-flowered, a foot high, and blooming in June and July; the elegant, *S. elegans*, a rare species, quite recently become known; and the hirsute, *S. hirsuta*, on mountains, flesh-colour flowered, a foot high, and blooming in May and June. All these five species are herbaceous evergreens.

SAXIFRAGE (Burnet). See Burnet Saxifrage.

SAXIFRAGE (Golden). See Golden Saxifrage.

SCAB. A loathsome and troublesome disease in sheep, analogous to itch in man and to mange in horses and cattle. See the articles Acari and Mange. It is highly contagious and exceedingly mischievous, and always gives great annoyance upon a stock-farm, and sometimes causes considerable mortality. It may originate in filth and poverty; and, when once it gets among a flock, it is rapidly propagated by actual contact, and by the sound sheep lying upon the spots and rubbing upon the posts which have been touched by the affected. It generally first reveals itself to the shepherd by the sheep becoming so itchy as to rub themselves upon posts or rocks or walls

or any other convenient objects,—a symptom which does not appear till about 12 days after the infection has been received; but it may, on examination, be detected much earlier by unnatural redness and floridness of the skin. It progresses from irritation to pustular eruption; and when the extreme itching and the rubbing begin, the skin is already rough and dotted with hard pimples; and in a few days, the pustules break, sores occupy their place, and scabs are formed; and, in the farther process of rubbing and exposure, the scabs are removed, the sores are aggravated and extended, the wool is denuded, maggots may begin to assist the horrible devastations of the acari, deep sinuses may be formed, and either incurable ulceration or total exhaustion may render speedy death inevitable.

"Although fat sheep, or those in improving condition, seem less liable to be attacked with scab than others, it is not, as some have supposed, a disorder in the blood, and to be cured by change to richer pasturage. It is strictly a cutaneous and local disease, although, like other local complaints, it will seriously and even fatally injure the constitution if not checked in its early stages. If speedily discovered, sulphur ointment will prove a remedy; but in more serious cases, in order to effect a cure, it is necessary to dress the sheep with mercurial ointment, which operation is performed according to the following directions:—Divide the wool into two parallel lines, about 2 and 4 inches from the back on both sides, and also one line down the shoulders and thighs; lay on the ointment close to the skin with your fore-finger as you make the divisions; lay another furrow or line down the throat, under the belly, and between the fore and hind legs; at the same time examine carefully for the affected parts, and dress them. Three pounds of an ointment, formed of 1 lb. of quicksilver, ½ lb. of Venice turpentine, 5½ lb. of hog's lard, and ½ lb. of resin, are sufficient for a score of large sheep, and two pounds and a half for hoggets or sheep in low condition. Highly useful as this preparation is for the cure of so troublesome a complaint, and much as it is recommended, yet there is scarcely a farmer that has used it without the loss of sheep from its injudicious application. October and March are the proper months for dressing, when the weather is dry; nor should it be delayed to a later season. In hot weather, the absorbent vessels carry it too quickly into the system, and the sheep become salivated, and also in the winter, from lying on the cold and wet ground. It is also highly dangerous to use it on ewes before or after lambing; nor is it safe at any time to anoint sheep that are poor or weak. But the following infusion will answer the purpose when it is improper to use the mercurial ointment:—Boil half a pound of tobacco in two gallons of water until reduced to one; strain and then add half a pint of spirit of turpentine, and half a pound of flowers of sulphur. On the application of this mixture, the scabs should be broken, and every affected part well searched and dressed. As this decoction, as well as the ointment, stains the wool and disfigures the sheep, immediately after they are shorn, a lotion of one ounce of corrosive sublimate, ¼ of a pint of spirit of wine, and 3 quarts of spring water may be used, first washing the animal well with soft soap and warm water. Every infected sheep should be removed from the flock as soon as dressed, and until there is a satisfactory proof of its convalescence. Even here, however, the anxiety of the farmer is not at an end. The complaint is probably more contagious than any other that can be mentioned. It has often happened, that, after all the stock has been sold and replaced, the new comers have been speedily infected. This is occasioned by coming in contact with the fences against which the diseased sheep have been in the habit of rubbing themselves; the wool left on the posts retaining some of the eggs or larvæ of the vermin, and of course communicating them to the new flock. The prudent farmer should, therefore, cause all flakes of wool remaining on the hedges to be carefully collected by his boys, and he should also remove all useless posts, and paint or tar the gates, or wash them with a solution of the chloride of lime, before he uses the same pastures again. Some complaints have been erroneously confounded with the scab, and much inconvenience and even mischief has arisen from the mistake, all the usual remedies to avoid contagion being taken unnecessarily. Hard and scurfy eruptions, and some species of the ticks, have been considered to be scab, and treated accordingly. The shepherd will be guided in his judgment by the actions of the sheep; if he observes that the painful itching and incessant rubbing are wanting, he may safely conclude that the attack is not scabby in its character. In some parts of the country, the scab in its most virulent form is known by the name of 'wildfire.' It becomes a species of erysipelas."

SCABIOUS,—botanically *Scabiosa*. A genus of ornamental plants, of the teasel family. The majority of the species which formerly constituted it, and which rendered it a large genus, are now assigned to the genera succisa, cephalaria, and pterocephalus. But one British species and nearly 20 hardy introduced species, three of them annuals, and the rest radical herbaceous perennials, still belong to it.

The indigenous species, *S. arvensis*, occurs in corn-fields and pastures, and is one of the most beautiful of our wild plants. Its root is perennial; its stem is annual and bristly and about 2 or 3 feet high; its radical leaves are stalked, lanceolate, and serrated; its cauline leaves are sessile and pinnatifid; and its flowers are large and handsome, and have a fine pale purple colour, and bloom from July till October. This herb has a bitter and nauseous flavour, and is disliked

by cattle, yet is eaten by sheep and goats. A white-flowered variety of it, *S. a. flore-albo*, occurs in gardens.

SCÆVOLA. A genus of ornamental exotic plants, of the goodenia tribe. Two evergreen herbaceous species about 20 inches high, and 6 or 7 evergreen ligneous species of from 20 to 40 inches in height—the former propagable by radical division, the latter from cuttings, and all loving a soil with some mixture of peat—have been introduced to the greenhouses and hothouses of Britain, principally from Australia and India; and nearly 20 more are known. The flowers of most are white; and those of the rest have some shade of blue or red.

SCALLION. See ONION and SHALLOT.

SCAMMONY. See BINDWEED.

SCANDIX. A genus of white-flowered, annual plants of the umbelliferous order. Venus's comb or the shepherd's needle, *Scandix pecten*, is a common troublesome weed of the corn-fields and other cultivated lands of Britain. Its root is tapering; its stems are simple but bushy, spreading, furrowed, leafy, and from 6 to 12 inches high; its leaves are light green and trebly pinnatifid; its leaflets are linear, acute, and smooth; its umbels are small, simple, solitary or in pairs, and chiefly terminal; and its fruit is nearly smooth, and has a bushy edge, and sends out a beak like a large needle to the length of one or two inches.

SCANTERING. See DIARRHŒA.

SCARCEMENT. A projecting slope from the base of an earthen fence, or from the line or level of a bank along which a hedge is planted. Scarcements were recommended by the old writers on hedging; but are now regarded, by all good judges, as serving no good purpose, and as encouraging a rank and noxious growth of weeds.

SCARIFIER. See GRUBBER.

SCARLET RUNNER. See KIDNEY BEAN.

SCHEDONORUS. A genus of grasses of the glyceria tribe. Five species are indigenous in Britain; at least a dozen species have been introduced from other countries; and about 20 more are known. The majority of the species at present in Britain are ranked by all the older botanists as fescues, and have been noticed in our article FESTUCA; and the others, even when viewed in the aggregate, do not possess much economical interest, and comprise only three which have any noticeable claim to the status of agricultural plants; and these three are, *S. deciduus*, a perennial indigen of the moist meadows of Britain, about 20 inches in height,—and *S. poæformis*, and *S. nigrescens*, both perennials of about a foot in height, introduced in 1819 from Switzerland. The name schedonorus signifies "near to a mountain," and alludes to the habitat of some of the principal species.

SCHEUCHZERIA. A curious evergreen herbaceous plant, of the order Juncagineæ. It occurs in the marshes and wet spongy bogs of some parts of England, but is very rare. It constitutes a genus of itself; and takes the specific name of *palustris*. Its root is creeping; its herbage is smooth, and has a white, shining, lax cuticle; its stem is erect, wavy, simply racemose, and 4 or 5 inches high; its leaves are few, sheathing, and cylindrical; and its flowers grow in a terminal cluster of about five, and have a brownish green colour, and bloom in May and June.

SCHINUS. A genus of ornamental exotic plants, of the terebinth tribe. The Peruvian species, or Indian mastic, *S. molle*, is an evergreen shrub of Peru and Mexico, and was introduced to the gardens of Britain toward the close of the 16th century. Its stem is from 8 to 12 feet high, and divides into many branches; its bark is dark brown; its leaves are alternate and pinnate, and have each from 10 to 15 pairs of leaflets, and a comparatively long terminating odd one; its leaflets are about $1\frac{1}{2}$ inch long and $\frac{1}{4}$ of an inch broad, and taper to the point, and are somewhat sawed on the edges, and have a lucid green colour, and emit a turpentine odour when bruised; and its flowers are very small, odourless, and of a greenish white colour, and grow in loose bunches at the end of the branches, and bloom in July and August. This plant requires a soil of rich mould, and is propagated from seeds or layers. Its leaf-stalks, when broken, and also the entire leaves of the nearly allied terebinthaceous plant, *Duvaua latifolia*, exhibit a curious and beautiful phenomenon when thrown into water,—the former producing numerous, tinted, floating, star-like figures which move about like dancers in a ball-room or like the ships of a fleet in manœuvring, and the latter starting and jumping up as if they were alive, and, at the instant of each start, discharging a jet of oily matter into the water. "This circumstance," says Dr. Lindley, "appears to be owing to some peculiar irritability of the parenchyma of the leaves, which, when acted upon by water, causes the turpentine sacs, that abound in the leaves, to empty themselves with violence; and the movements of the leaves may be ascribed to the recoil produced by the discharge. Thus we have in every leaf a sort of vegetable battery, which will keep up its fire until the stock of ammunition is expended."

SCHISMUS. A small, hardy, annual grass, of the oat tribe. It was ranked by Linnæus as a fescue; but it now constitutes a genus of itself, and is specifically called *marginatus* or the margined. It is a native of Spain, and was introduced to Britain nearly 70 years ago. It has a height of only 6 or 7 inches.

SCHIZANTHUS. A genus of ornamental, hardy, annual plants, of the figwort family. The name signifies torn-flower; and alludes to deep and numerous indentations in the borders of the corolla; and is very descriptive. Five species,—the pinnate, the spreading-stalked, Graham's, Hooker's, and the retuse-petaled—

were introduced to Britain from Chili about 20 or 24 years ago; and some other species and varieties have been obtained since that time; and all are handsome and delicate, and well deserve a place among the choicest annuals of the open garden. They have a height of from 12 to 24 inches; and carry a great profusion of flowers; and thrive best on a light loamy soil. The flowers of most are variegated in colour; and those of the several species have a predominance of either red, scarlet, lilac, rose, purple, or white.

SCHIZOPETALON. A small genus of ornamental exotic plants, of the cruciferous order. Walker's species, *S. Walkerii*, is a curious and interesting annual, and carries white flowers during about two months, and was introduced to Britain in 1822 from Chili. The name schizopetalon signifies 'torn petal,' and is descriptive.

SCHMIDELIA. A genus of tropical, ornamental, evergreen shrubs and trees, of the soapberry tribe. Four species, varying in height from 8 to 25 feet, and all white-flowered, and loving a soil of peaty loam, and propagable from cuttings, have been introduced to British collections from the East and West Indies; and upwards of a dozen more are known.

SCHMIDTIA. A small, curious, hardy, annual grass, of the agrostis tribe. It constitutes a genus of itself, and was introduced to Britain about 28 years ago from Bohemia.

SCHŒNUS. See Bog-Rush.

SCHOTIA. A genus of ornamental, crimson-flowered, Cape-of-Good-Hope, evergreen shrubs, of the cæsalpinia division of the leguminous order. Four or five species, of 5 to 6 feet in height, and mostly continuing in bloom through the greater part of summer and autumn, have been introduced to British gardens; they require a higher degree of heat than most Cape plants, and thrive best in a soil of peaty loam.

SCHUBERTIA, or Taxodium. A small genus of ligneous plants, of the coniferous order. It consists of two species which were formerly ranked as cypresses; and it differs from the cypress genus, both in habit of growth and in the arrangement of its inflorescence,—its male flowers forming long, loose, pendulous catkins, somewhat branched near their base, and its female flowers being scarcely apparent, and existing in small and almost sessile clusters.

The two-rowed schubertia, or deciduous cypress, or North American deciduous cypress, *Schubertia disticha* or *Taxodium distichum*—formerly called *Cypressus disticha*—is a native of the swamps and wet alluviums of Virginia, Florida, Louisiana, and other parts of North America, and was introduced to Britain before the middle of the 17th century. It covers vast tracts in its native regions; and gives them the popular name of Cyprieres; and sometimes attains a height of about 120 feet; and has generally a conical form of stem, with a girth 3 or 4 times greater at the base than toward the top; and has sometimes so vast a basal girth as from 20 to 40 feet. In Britain it is quite hardy; and requires a place in the moistest part of a plantation, or by the side of a rivulet, or spring, or pond; and commonly attains a height of from 30 to 60 feet. It grows conically while young; but becomes wide-spreading and often flat-topped when old. It presents some resemblance to an evergreen in summer, and has very pleasing foliage, not unlike that of some kinds of acacia, and is, therefore, well fitted to decorate certain parts of ornamental grounds. Each leaf is from 4 to 5 inches long, and has a midrib and two opposite rows of leaflets, and is of a pleasant light green colour in summer, and changes to a dull red in autumn. The leaflets are narrow, straight, fine, and slightly concave on the upper surface, and generally fall before the midribs. The full-grown cones are nearly globular and fully an inch in diameter, and have thick and woody scales, rounded at the outer extremity. The seeds are small, hard, and irregularly round; and comprise each six or seven cotyledons. The timber has a reddish colour, and is elastic, strong, and durable, and neither so heavy nor so resinous as the timber of the pines. This tree is one of the most important timber trees of North America; but is not suitable to be grown in Britain, except for ornament or in warm, sheltered, swampy nooks, upon a soil of sandy peat. It may be propagated either from seeds in the same manner as the common cypress, or from cuttings planted in a moist sandy soil in October. Five very distinct varieties of it, all propagable from seeds, occur in British collections, —the spreading, the lofty, the drooping, the Chinese, and the pendulous; and the two last of these are natives of respectively China and South America.

The Cape schubertia, or African cypress, or juniper-like cypress, *Schubertia capensis* or *Taxodium capense*—called by Linnæus *Cupressus juniperoides*—is an evergreen shrub of commonly about 6 or 7 feet in height; and was introduced to Britain, about 90 years ago, from the Cape of Good Hope. Its branches are numerous and slender, and spread themselves all around; its leaves are opposite, narrow, awl-shaped, of a light green colour, and about an inch in length; and its flowers come out from the sides of the branches, and bloom in April and May, and are succeeded by black fruit.

SCILLA. See Squill.

SCIRPUS. See Club-Rush.

SCITAMINEÆ. A natural order of monocotyledonous plants. It is nearly allied to the orchidaceous order, but differs in its pollen not cohering in masses, in its ovary being plurilocular, and in its seeds not being winged. It occurs only within the tropics, and consists almost wholly of stemless or caulescent herbs, with long broad leaves, and with white, yellow, or red flowers, most of which are beautiful, and not

a few delightfully fragrant. The roots and seeds of most of its species are more or less aromatic; and those of some—such as the roots of ginger and the seeds of cardamon—occupy a most distinguished place among the aromatics of the materia medica. Nearly 150 species, belonging to 11 or 12 genera, have been introduced to the gardens of Britain; and nearly all require hothouse culture.

SCLERANTHUS. See KNAWEL.

SCLEROCHLOA. A genus of hardy, annual grasses of the fescue tribe. The procumbent species, *S. procumbens*, is a weed of the sea-coasts of Britain, and has a height of 6 or 7 inches, and blooms in July and August; and the rigid species, *S. rigida*, is a weed of sandy grounds in Britain, and has about the same height as the preceding, and blooms in June and July. These two species are popularly called hard grass; and are assigned by some botanists to the genus poa. Four species—but none of them economically interesting—have been introduced from other countries.

SCOLOPENDRIUM. See HART'S TONGUE.

SCOLYMUS. See GOLDEN THISTLE.

SCOLYTUS. A genus of the xylophagous family of beetles. It is distinguished, along with the genera tomicus, hylurgus, and hylesinus, for its devastations upon timber. See the article BOSTRICHIDÆ. It has nine joints in the antennæ below the club, strong and obtusely triangular mandibles, short and four-jointed maxillary palpi, cylindrical body with the apex of the abdomen obliquely truncated, and four-jointed tarsi.

The destroying scolytus, *S. destructor*, has excited vast attention on account of its enormous devastations upon avenues and groves and plantations of elm. The perfect insect is black and shining, and about $2\frac{1}{2}$ lines long; its head is clothed with short yellowish hairs; its thorax is large and finely punctured; its elytra vary in colour from almost black to almost chestnut, and have each seven punctured striæ; its abdomen is hairy; and its legs and antennæ are dull red. The larva is a small, white, fleshy grub, destitute of legs, and pretty similar in appearance to the larva of the nut weevil; its head is smooth and horny, and has no antennæ; its jaws are obtuse and strong; its body is curved into a semicircle; and the segments are transversely channelled. This insect, though for 12 or 15 years past threatening many of the elm plantations of England and of the environs of the principal cities of northern continental Europe with extermination, was not known to entomologists as an elm destroyer till about the year 1824. Extensive injuries inflicted by it, in St. James' Park, Hyde Park, Greenwich Park, Camberwell Grove, and other parks and promenades around London, were ascribed to human malice or misconduct, and occasioned angry excitement and legal investigation, but eventually suggested inquiry by competent naturalists under the authority of government, and led to the full discovery of the true cause. An indiscriminate felling and uprooting of many thousands of diseased trees was resorted to for extirpating the insect, but was found to produce little or no effect; and the signal failure of so very costly and deplorable a resource urged investigators onward to the eventual discovery of a true though still costly remedy. Erosions are made by the female beetle and by the larvæ in the bark, the inner bark, and the alburnum; and whenever these become very numerous, they so greatly interrupt the ascent of the sap and the descent and assimilation of the cambium as to cause the death of the tree. "The female insect commences its injury about July by boring through the bark, until she has reached the part between the soft wood and inner bark, when she forms in the latter a vertical channel usually upwards of two inches long, on each side of which she deposits her eggs as she advances to the number of from 20 to 50. About September the larvæ are hatched, when they commence feeding upon the matter of the inner bark, at the edge of the channel, and in a very slight degree on that of the soft wood opposite, advancing as they feed, in a course of about right angles from the primary channel and on each side of it. When the larva has finished its course of feeding, it stops in its progress, turns to a pupa, and then to a beetle; after which it gnaws a straight hole through the bark and comes out. The beetles come out about the latter end of May, in the year following that in which the eggs are deposited; the sexes afterwards pair, and the female, bearing eggs, bores through the bark, and so on from generation to generation, and from year to year. The infested trees may be easily recognised, as the bark will be found perforated by small holes, as if made by a shot or broad-awl, in several parts, whilst small particles like saw-dust will be found on the rough surface of the bark, and at the foot of the tree. The scolyti never attack dead trees; they seldom destroy the trees they attack, the first year that they commence their ravages; and they prefer a tree that they have already begun to devour, to a young and vigorous tree. It is stated that at least 80,000 have been known to attack a single tree. From observations made, it appears that the females never deposit their eggs in trees perfectly healthy, but that both they and the males pierce young and healthy trees for the purpose of eating the inner bark which constitutes their food, and that the numerous holes they thus cause, partly from the loss of sap which exudes from them and the absorption of rain which lodges in them, will bring the trees in which they occur into that incipient state of ill health, in which the females select them for laying their eggs, and that thus healthy trees are effectually destroyed by the combined operations of the scolyti of both sexes, though not solely in consequence of the depositure of

the eggs of the female. The practical directions resulting from a knowledge of the economy of the scolytus when there is reason to suspect its presence, are first to pare away the exterior rough bark with a cooper's spokeshave or other convenient tool, thus admitting of a distinct inspection of the actual state of the trees, which, if having no trace in the inner bark either of small holes in old trees, or those superficial furrows which they make for food in young trees, may be pronounced sound and healthy, and to require no further attention. If the inner bark should exhibit any of these appearances, it is next to be ascertained whether the female has already deposited her eggs in it, and if it contain larvæ, (which may be known by cutting away portions of the bark down to the actual wood,) should their existence be proved, the trees should be cut down, the bark peeled off, and every fragment carefully burnt. Trees which have been merely pierced for food, may be carefully brushed over with coal tar, the smell of which is highly offensive to the insect; and when this is repeated for a year or two, they are enabled to resume their vigour, and grow healthy."

The drawf scolytus, *S. pygmæus*, is sometimes associated with the preceding species in the work of ravaging the elm, but is more generally, and somewhat distinctively, a devastator of the oak. Its length is not more than one line and a half; its body is black, smooth, and shining; its head is strong and granulated; its thorax with the anterior margin is sometimes reddish; its elytra are rust red and closely punctate-striate; its abdomen is retuse; its legs are pitch-red; and its antennæ also are red, but of a lighter hue than the legs. This insect abounds in France, and made such havoc on a somewhat recent occasion, in the Bois de Vincennes that 50,000 young oaks had to be cut down in consequence of its attacks; and though hitherto undetected in connexion with any devastation in Britain, it may possibly, at some future day, make as sudden and desolating an appearance among the oaks of our country as the destroying scolytus has done among the elms, and requires therefore to be known.

SCOPULA. See Pyralis.

SCORPION-GRASS,—botanically *Myosotis*. A genus of ornamental herbaceous plants, of the borage family. Seven species grow wild in Britain; upwards of a dozen have been introduced from other countries; and between 20 and 30 more are known. Some are annuals, and others radical perennials; some are aquatics, and others frequent very dry situations; some are trailing or procumbent, and others are more or less upright; some possess little interest, and others are among the most exquisitely beautiful small-flowered plants in the world. The great majority have blue flowers; and all the very handsome ones are well represented by the well-known perennial-rooted indigenous species noticed in our article Forget-Me-Not. All the species, when grown in gardens, will thrive in any common soil; and most of the perennial ones are propagated by radical division, and all the annual ones, and the rest of the perennials, from seeds.

The tufted scorpion-grass, *M. cæspitosa*, is an indigen of watery places in Britain. Its roots are perennial; its stems are 9 or 10 inches high; and its flowers are blue and very beautiful, and bloom in June and July. A long calyxed variety of it, *M. c. macrocalyx*, occurs wild.—The intermediate species, *M. intermedia*, is an indigen of the dry woods of Britain. Its roots are perennial; its stems are procumbent and about 6 inches long; and its flowers are very handsome, and bloom in April and May.—The rock species, *M. rupicola*, is an indigen of rocky situations on the lofty mountains of Scotland. Its roots are perennial; and its flowers are blue and beautiful, and bloom in June and July.—The wood species, *M. sylvatica*, is a perennial-rooted weed of the woods of Britain. It has a height of about a foot, and blooms in June and July.—The corn-field species, *M. arvensis*, is an annual, blue-flowered weed of the dry fields of Britain. It has a height of about a foot, and blooms from spring till autumn. A handsome white-flowered variety of it, *M. a. alba*, occurs in gardens.—The party-coloured species, *M. versicolor*, is also an annual weed of the dry fields of Britain. Its stems are about a foot high; and its flowers are blue and yellow, and bloom from April till June.

The Azorean species, *M. azorica*, grows about waterfalls, streams, and wet rocks in some of the westerly islands of the Azores, and was introduced to Britain in 1844. It is a perennial, scarcely hardy, about two feet high; and it resembles our native forget-me-not, but has larger flowers, of a deep indigo blue colour, and is more prolific of bloom on its numerous lateral branches. It needs a moist atmosphere.—The dwarf species, *M. nana*, was introduced about 48 years ago from Continental Europe. It also is a perennial, and presents a close resemblance of flower to the forget-me-not; but blooms only for a short period, and is only 4 or 6 inches high, and has the recommendation, while in bloom, of displaying a great profusion of flowers comparatively to the bulk of its herbage.

SCORPION SENNA. See Coronilla.

SCORPIURUS. See Caterpillar.

SCORZONERA. A genus of exotic herbaceous plants, of the succory division of the composite order. About 30 species—all hardy, chiefly perennial-rooted, mostly yellow-flowered, and varying in height from 6 inches to 3 or 4 feet—have been introduced to Britain; and a few more are known. Most of the introduced species are more or less ornamental, and flourish on any ordinary soil, and may be propagated either from seed or by radical division.

The Spanish species, *S. hispanica*, was introduced in the latter part of the 16th century; and

has long been cultivated in kitchen gardens for the sake of its esculent root; but is now in much less request than at former periods. Its root is carrot-shaped, and about the thickness of a finger, and is white within, and has a milky juice, and is covered with a dark brown skin; its stem is smooth, and branches at the top, and is garnished with a few half-sheathing leaves, and has a height of about 3 feet; its lower leaves are acutely pointed, waved and sinuated, and about 9 or 10 inches long and 1½ inch broad in the middle; its upper and half-sheathing leaves are linear; its flowers grow in scaly calyxes, and comprise many narrow tongue-shaped florets, lying imbricatedly like the scales of a fish, and have a bright yellow colour, and bloom from June till September; and its fruit contains a mass of oblong cornered seeds, and has at the top a roundish ball of feathery down. This plant is raised, for culinary purposes, from seed sown in April or May; and must, for prolonged use, be raised in proper succession, as it sometimes runs to seed in the same year in which it is sown. It thrives in any common soil; and it may be sown either broadcast or in drills, but must be thinned out to distances of about a foot from plant to plant. The roots of plants sown in April and May are in full growth for use in autumn and winter; and they are eaten boiled. The name scorzonera is derived from a word signifying "viper;" and both it and the popular name of viper-grass were given to the plant in allusion to some fancied medicinal power.

SCOTCH ASPHODEL,—botanically *Tofieldia Palustris.* A curious, indigenous, evergreen herb, of the melanthium tribe. It grows wild on upland bogs, and on the marshy banks and neighbourhoods of pools and rills. Its root is woody; its stem is solitary and about 4 inches high; its leaves grow in two-ranked radical tufts, and are ensiform, ribbed, incurved at the point, and about two inches long; and its flowers are produced at the top of the stem in a small oblong spike or head, and are greenish-white and inodorous, and bloom in July and August.

SCOTCH FIR. See PINE.

SCOTCH KALE. See BORECOLE.

SCOTCH LABURNUM. See LABURNUM.

SCOTCH LILAC. See LILAC.

SCOTTIA. A genus of ornamental, Australian, evergreen shrubs, of the genista division of the composite order. Two species, both about 3 feet high, the one with red and green flowers, and the other with yellow and scarlet flowers, have been introduced to the greenhouses and conservatories of Britain.

SCOURING. See PURGING, DIARRHŒA, and DYSENTERY.

SCRATCHES. Troublesome ulcerations about the heels of horses, occasioned by ill-treatment, negligence, and filth. They are a virulent kind of cracks, and are frequent concomitants of grease. See the article GREASE.

SCREENING. The sifting of earth or seeds or mixed dry substances through a large oblong sieve or riddle, called a screen.

SCREW-PINE. See PANDANUS.

SCREW-TREE, — botanically *Helicteres.* A genus of ornamental, tropical, evergreen shrubs, of the bombax family. Nearly a dozen species, varying in height from 6 to 14 feet, have been introduced to the hothouses of Britain; and some more are known. The leaves of some are heart-shaped and marshmallow-like; and the flowers of most are either red, brown, purple, yellow, or white. The Isore species, *Helicteres isora,* may be regarded as the type of the whole genus; and has the rank in India of a medicinal plant, and was introduced to Britain in 1733. It attains a height of 12 or 13 feet, and is very branchy or bushy, and carries yellow flowers in June and July. Its root and its fruit are the medicinal parts;—and the latter is a contorted capsule, consisting of five fibres twisted in the shape of a screw; and varies in length from one inch to 2½ inches; and is alluded to in both the popular and the botanical names of the genus,—the latter being formed from a word which signifies a screw. The juice of the root has the reputation, among some Indian pharmacists, of being a powerful stomachic; and a liniment, prepared with the powder of the fruit, is supposed to be a valuable application in cases of offensive sores inside of the ears. All the species of screw-tree in British collections love a soil of peaty loam, and are propagable from cuttings.

SCROPHULA. A deep-seated and malignant cutaneous disease, popularly called the king's evil. The name is derived from a word signifying a sow, and was suggested by the fact of swine being subject to the disease. But sheep also are sometimes attacked with a very virulent kind of scrophulous malady, which, in their case, is sometimes called 'the evil,' and sometimes bears other names. This malady is first indicated by a hard swelling of the glands under the jaws; it afterwards throws out about the head and the neck, a succession of small pustules, which break, and discharge a white matter, and heal, and multiply; and it eventually debilitates and emaciates its victims till they sink into irretrievable weakness and die. It rarely attacks more than a few individuals of a flock. The only known remedy for it is iodine; and this has been somewhat successfully used in the forms of hydriodate of potash administered in a daily dose of 4 or 5 grains in gruel, and of ointment of iodide of mercury rubbed upon the pustulated parts.

SCROPHULARIA. See FIGWORT.

SCUFFLER. See GRUBBER and HARROW.

SCURVY-GRASS, — botanically *Cochlearia.* A genus of herbaceous plants, of the cruciferous order. Four species grow wild in Britain; 9 or 10 species, all hardy, and chiefly white-flowered and but a few inches high, have been introduced from other countries; and about 20 other species

are known. The four indigenous species comprise the main interest of the genus; and the most important one of these is noticed in the article HORSE-RADISH.

The officinal scurvy-grass, *Cochlearia officinalis*, occurs on the sea-shores and on some of the uplands of Britain, particularly in the north-west of England. It is a biennial, of fleshy texture and smooth surface, and varies greatly in height, yet is most frequently about 6 or 7 inches high. Its stem is angular, leafy, and branching; its radicle leaves stand on long footstalks, and are kidney-shaped, subdentate, and spreading; its cauline leaves are alternate, sessile or sheathing, oblong, and angularly sinuated; its flowers grow in terminal corymbs, and have a white colour, and bloom in April and May; and its fruit are globose silicles, each crowned with a very short style and somewhat roughish. The fresh plant is eaten in the way of salad, as a stimulant, a diuretic, and an antiscorbutic; it has a bitter acrid taste, and emits a pungent odour when bruised; and it yields by distillation a volatile oil and sulphuretted hydrogen. The dried herb, however, whether in itself, or in powder, or in infusion, has none of the active properties or taste or flavour of the fresh herb. Two varieties of a somewhat ornamental character occur wild,—the smaller, *C. o. minor*, and the round leaved, *C. o. rotundifolia*. The plant is raised in the kitchen garden from seed, sown in a damp sandy soil, early in the autumn, in drills 8 inches apart.

The English scurvy-grass, *C. anglica*, is an annual indigen of the sea-shores of Britain, and has a height of 6 or 7 inches, and blooms in May. —The Danish scurvy-grass, *C. danica*, is also an annual indigen of the sea-shores of Britain, and has a height of 3 or 4 inches, and blooms in May and June.—The Greenland scurvy-grass, *C. gronlandica*, is a biennial indigen of some of the lofty mountains of Scotland, and has flesh-coloured flowers and a height of 6 or 7 inches, and blooms in May and June.—All these three species, as well as the officinal scurvy-grass, have an economical character.

SCUTELLARIA. See SKULLCAP.

SCYTHE. An implement for mowing. A general view, both of the common scythe for cutting down herbage crops, and of the cradle scythe for cutting down corn crops, has been given in the article MOWING; and any particular account, descriptive of the many varieties and modifications of each kind, seems unnecessary; for districts of country and individual mowers are so firm in their respective tastes and so wedded to their respective habits, that, for the most part, each works best with his own favourite varieties of the implement.

The common grass scythe does very well for mowing upright crops of oats and barley; but even when furnished with a bow, it cannot lay evenly down a heavy crop of wheat, or duly deposit it at right angles with the standing corn for the convenience of the binders. The cradle scythe is much modified in its powers and action by the form and comparative length of the handle, and by the form and materials and mounting of the cradle. Drummond's iron handled scythe is a very efficient implement in the hands of a good mower who likes it or has become accustomed to it, cutting down from $1\frac{1}{2}$ to $2\frac{1}{2}$ acres in the day, and serving equally well to "cut out" or to "cut in;" and the short-handled scythe of Aberdeenshire has a high provincial reputation, especially for the mowing of heavy or of lodged crops. The Hainault scythe, an implement of medium character between the true scythe and the sickle, is noticed in the article HAINAULT SCYTHE. See also the articles REAPING, HAY-MAKING, and SICKLE.

SEA-BANK. See EMBANKMENT.

SEA-BLITE. See GOOSEFOOT.

SEA-BUCKTHORN. See BUCKTHORN (SEA.)

SEA-DAFFODIL. See PANCRATIUM.

SEA-HEATH. See FRANKENIA.

SEA-HOLLY. See ERYNGO.

SEA-KALE,—botanically *Crambe*. A diversified genus of plants of the cruciferous order. One species grows wild in Britain; nearly a dozen species have been introduced from other countries; and several other species are known. About one-half of the species in Britain are hardy tuberous-rooted herbs, and have the lower joint of the silicle thick and depressed; three or four are hardy annuals or biennials, and have the lower joint of the silicle elongated and cylindrical; and two are greenhouse evergreen undershrubs, and have the lower joint of the silicle short and filiform. The tartarian species, *Crambe tatarica*, a tuberous-rooted, white-flowered herb, of about 3 feet in height, blooming in June and July, and introduced to Britain about 60 years ago from Siberia, is a culinary plant; and the heart-leaved species, *Crambe cordifolia*, a tuberous-rooted, white-flowered herb, of 6 or 7 feet in height, blooming in May, and introduced about 26 years ago from Caucasus, possesses a somewhat ornamental character; but all the other introduced species are comparatively uninteresting.

The indigenous or common sea species, *Crambe maritima*, concentrates in itself the main interest of the genus, and often makes a complete monopoly of its name. This plant inhabits the shingles and rocks and cliffs and sandy downs of the shores of the south and west of England, of some parts of Scotland, and of Denmark and Sweden. Its roots are large, tuberous, fleshy, and much divided at the crown, and spread so much underground as rapidly to propagate the plant; several stems rise from each root, or set of roots, and are branched, spreading, and leafy, and have a height of from 12 to 24 inches; the leaves are stalked, spreading or deflexed, large, undulated, toothed, of a leathery texture, very glaucous, smooth, and rather succulent,—the lowermost

somewhat lyrate, and the rest roundish acute; the flowers grow in dense terminal clusters, and are fragrant and have a milk-white colour with a yellowish centre, and bloom in May and June; and the silicles are round, smooth, and about the size of black currants, and contain each a single seed.

The inhabitants of the coasts on which sea-kale grows wild have, from time immemorial, been in the habit of searching for its young shoots as they emerge from the sand and gravel, and cutting them under the surface, and using them as a highly esteemed and delicate pot vegetable. Boys also procure them, in a hazardous manner, from the crevices of sea-cliffs, by letting themselves down from above with ropes. Yet sea-kale, in all the circumstances of its wild condition, even when obtained in the most tender and blanched state, is merely a species of green kale; while it can be rendered by culture an exceedingly delicate vegetable, of the same category of esculents as asparagus, but preceding that choice plant in the season, and combining much of its peculiar flavour with that of the best borecole or chou de Milan. The young spring shoots rising from the root are the chief parts used; and they have a thick substance, and, when artificially well blanched and cut in a sufficiently early stage of their growth, they are both tender and finely flavoured. The ribs of the large leaves, also, are peeled and dressed like asparagus.

Sea-kale was sent from England to the Continent, by Lobel and Turner, before the middle of the 16th century; yet it was botanically described for the first time by Miller in 1731; and was not brought into repute as a garden vegetable till Dr. Lettsom introduced its cultivation in 1767. But it has now a place in almost every good or extensive private kitchen garden; and it forms a profitable article of attention with market-gardeners, generally meeting a ready sale, and bearing a comparatively high price. It requires some peculiarity of treatment, yet can be quite easily cultivated; and, while so perfectly hardy as to withstand any ordinary frost, it is one of the finest possible subjects for forcing, always possessing more crispness and delicacy when forced than when raised in the natural way. It can be raised from seeds, and brought to the table early in the second year after sowing; and it can likewise be multiplied, and modified, and propagated abundantly, at any season of the year, by means of offsets from the shoots or division of the roots, and then transplanted, trenched, and blanched. The following directions for cultivating it are taken from a paper by Mr. Towers, the well-known author of the Domestic Gardener's Manual:—

"The soil, as indicated by the native situation and habits of the plant, should be light and sandy, with a slight addition of mild lime, muriate of soda, and wood ashes. The beds ought to be prepared as for asparagus; and of a light sandy turf, with a natural manuring of sea-weed alone, or artificially with one-fourth of a compost consisting of perfectly reduced fern, or leaf-mould, nine parts, wood ashes, one part, and about half a pound of common salt to every barrow-load of the compost. This last chemical compound contains a large proportion of the components of sea-water, and the wood ashes yield carbonate of lime in its most effective state, also some carbonate of potash and fine silex. Three barrows of light sandy turf, and one barrow of the above compost, give proportions which promise to yield a medium of growth of the most permanent and effective character. In it sea-kale and asparagus might be grown for forcing, either side by side, or in separate plots. But if neither turf nor sea-weed can be obtained, good kale can be produced in any light garden soil, trenched in the same manner as for asparagus beds, and manured copiously with wood (not coal) ashes, and the prescribed quantity of common salt. All the difference in the two beds is this, that for sea-kale, or forced asparagus, the plot of ground should be large enough to permit the plants to stand in single rows 3 or 4 feet apart. The rows may be of any required length according to the quantity likely to be consumed. Supposing that 6 or 8 rows, each 12 feet long, be required, then the ground is either to be trenched 20 inches deep at the least, or dug out and replaced with the enriched turf; and the work ought to be completed before March, so as to become settled by the middle or latter end of that month. Between every row there should two stakes be set up at each end, two feet asunder; these will mark the beds and the spaces between them; thus there may be 8 beds and 9 spaces or divisions. At the time of sowing the beds—(I greatly prefer seed to plants)—leave a space on the outside of two of the outermost stakes, and strain a garden line exactly along the middle of the bed immediately within, and next to it; and beginning at one end of the line—but a foot within it—make a small ring or circle with the finger, an inch deep, and three inches wide; or what is better, force a circular piece of iron or wood into the ground to the required depth, and drop three seeds in the ring so formed, equidistant, and at right angles with one another. Form and sow the rings about fifteen inches asunder—centre from centre, the whole length of the line; then cover the seeds to the surface depth with sand, and pat it to a level with the flat of a spade; one row or bed will thus be sown. Leave the adjoining space of two feet vacant; and proceed to the bed or division next beyond it: sow that, and proceed in the same alternate order till the plot be completed; when a space exterior of the last sown division must be left, and it will then be found that whatever be the number of divisions sown, that of the unsown spaces will exceed it by one. The plan thus laid down is grounded upon the practice of the celebrated Bath cultivators; and nothing can exceed it for the facility it affords to good tillage, and orderly, convenient forcing. If the seed be good, the season propitious, warm, and moist, germination will rapidly advance; and when the plants appear, they may be secured from vermin by sprinkling around and within them a good covering of wood ashes, three parts, blended with soot and powdered lime, of each one part. If weeds arise and threaten to surmount the plants, they must be kept under by surface-hoeing to the depth of an inch, with the Dutch or thrust-hoe. Perhaps three plants will rise from each ring, and these, and indeed all that grow, must remain till they begin to interfere with each other; then, one only, the strongest, must be left, and the others drawn or raised up; so that a complete row of single plants, from 1 foot to 15 inches apart, finally remain. The young supernumeraries may be set out in rows, to grow for succession, or be thrown away if no more stock be re-

quired. The plants in the rows will grow luxuriantly, and become very large, so much so as, in all probability, to come in contact, forming one connected line of sea-green foliage. All the culture during the summer and autumn, will consist in keeping the beds clear from weeds, and in digging the alternate spaces two or three times, to the depth of 9 inches, so as to pulverize and render the soil as fine as possible. At the two last operations (say in July and October), it would be as well to incorporate with the soil a two-inch layer of decayed leaves, mixed with one-fourth part of pure wood-ashes. The reader will be very careful to avoid sea-coal or even pit-coal ashes. It formerly was the custom to cover sea-kale with conical hills of those ashes during winter, and one out of three or four plants perished, the damage being ascribed to mice or moles. I never have lost a plant since I left off that acrimonious chemical compound, styled ashes, nor could I, by any means, keep my bed entire while I employed it. Its destructive influence has at length been admitted, and sea-kale now enjoys a regular growth, and repays its cultivator. No forcing ought to be attempted during the first winter; but it would not be amiss, after clearing off all the old leaves, to strain a line along the edges of the beds, and, cutting the earth by it three inches deep, to mould up the two feet beds with the earth taken to that depth from the intermediate spaces. A tall marking stick should, however, be placed near the centres of the plants. After the earthing up, a blanching-pot, wooden box, or old bee-hive, is to be set over every plant. A straw-hive is indeed an excellent material. It is sufficiently strong, warm, and impervious to light, even when used alone, without leaves, for blanching. A small or even a very tolerable gathering of fine white kale will be the result of this treatment, earlier or later, according to the season and climate; and, in cutting it, the knife should be passed below the surface of the stratum of soil that was added, so as to bring up each full-sized shoot in a compact state, and not in detached leaves. The smaller sprouts ought not to be cut; and, when all the large ones have been taken, the superposed soil should be drawn back into the spaces, and the whole plot reduced to an even surface-level. This work will, it is presumed, be performed about mid-April, and then a knife, or very sharp-edged spade, should be passed through the shoots, so as to cut off every one that rises above the original level of the bed. This cutting will induce the plants to send forth a number of fresh shoots, and prevent, in a degree, the protrusion of flower-stems. The routine culture of the second season will comprise weeding with a flat hoe, digging and enriching of the spaces, as before directed, and the immediate excision of every flower-stem that may be sent up. After the leaves have become inactive, remove them. Mark each plant with a tall stick, and dig and mould up the beds with fine earth from the spaces, as in the previous season; but now, and in each succeeding year, dig out, and remove to a spot at hand (as convenience may point out), the earth of each space, on the sides of those rows which are to be excited, so as to leave trenches one foot deep. The plots ought to be so contrived as to furnish three distinct forcings,—the first to commence late in November, to be cut at the close of the year; the second, about the first week in January; and the third, early in February. A fourth reserve ought to come in at the natural season, blanched, but not forced, in April. The trenches are to be filled to the level of the tops of the line of pots or covers with tree-leaves, blended, if possible, with one-third part of fresh stable-manure. When this level is attained, the pots and spaces between them must be covered to the depth of two feet with the same materials. The bed of fermenting material ought to form a compact mass of equal depth; and this it will be advisable to cover with straw hurdles or thatch, to keep out excessive rains, and to retain the developed heat. Trial-sticks should be thrust deeply into the masses; and if these, on being withdrawn, feel gently warm, the work of forcing will proceed regularly, and kale will be procured in succession from Christmas to the end of March, to be succeeded by the crops from the unexcited bed. After forcing and clearing off the leaves, &c., the trenches are always to be filled up, and the surface-level restored."

SEA-LAVENDER. See STATICE.

SEAM. Tallow, hog's lard, or any other prepared, solid animal fat; also, a quarter of grain; also, a horse-load of wood.

SEA-MATGRASS. The *Psamma arenaria* or *Ammophila arundinacea*. See ARUNDO.

SEA-MILKWORT, — botanically *Glaux*. A small, handsome, evergreen, indigenous plant, of the salicaria family. It constitutes a genus of itself, and takes the specific name of *maritima*. Its name glaux alludes to the colour of its leaves, and its name maritima to its habitat in salt marshes. It is also sometimes called black saltwort, in allusion to the saltishness of its taste. The stem is densely leafy, and 3 or 4 inches high; the leaves are entire, elliptico-oblong, and smooth; and the flowers are axillary, solitary, and nearly sessile, and have a flesh-colour, and bloom in May and June. The plant may be raised from seeds, and cultivated in an open sandy loam.

SEAM-PRESSER. See ROLLER.

SEA-MUD. See MUD and SEA-OOZE.

SEA-OOZE. The sediment of sea-water around bays and friths and the mouths of rivers. It is a compound of finely comminuted earths, calcareous matters, saline substances, and animal and vegetable remains; but materially varies in composition, as found in different localities, according to the form of the beach, the strength of the sea-water, the action of the winds and currents, and especially the character of the alluviums and drainages brought down by the adjacent rivers. It is, in every case, a good manure; but, on most soils and for most purposes, it acts best when it contains a fair proportion of calcareous matter, or freely effervesces with any of the common acids.

Sea-ooze has been extensively and advantageously used as a spring top-dressing for grass lands. It also does well, in some places, to be spread on old lea, and ploughed in, without any addition, in the following spring, preparatorily to a rotation of oats, potatoes, wheat, and either oats and barley with clover and grasses; and has been found, when used in this way, to produce great crops, and to exert a more durable and much less critical or doubtful influence than marl. It has likewise been employed, with mighty and very enduring effect, as a fertilizer of moss lands; but requires, in this capacity, to be applied in the large dose of about 100 one-horse cart loads

per acre; and is liable to prove comparatively inert if applied a second time to a piece of moss-land which it formerly fertilized.

A judiciously formed compost of sea-ooze with whatever earths or other substances are most suited to the condition and wants of the soil to which it is to be applied, serves as an excellent top-dressing for either grass or wheat in winter, and acts very fertilizingly on thin poor pastures, and effects surprising improvement on almost every kind of garden soil. "Sea-ooze, when applied to land in tillage," says Sir John Sinclair, "ought to be mixed with the soil, as soon as possible after being brought out of the water. One part of ooze and two parts of peat-moss, make an excellent compost. Of this, twenty cart-loads (about 1¼ cubic yard each) will produce an excellent effect upon an acre of land for barley, or indeed any kind of grain. Peat, when drenched in sea-water, is to be preferred. When peat cannot be got, the ooze may be compounded with earth and other substances."

SEA-PARSNIP. See SAMPHIRE (PRICKLY).

SEA-PIE. See OYSTER-CATCHER.

SEA-REED. See ARUNDO.

SEA-ROCKET. See CAKILE.

SEA-SAND. See SAND.

SEA-SHELLS. See SHELLS.

SEASIDE BALSAM. See CROTON.

SEASIDE GRAPE,—botanically *Coccoloba*. A genus of ornamental, evergreen, tropical shrubs and trees, of the polygonum family. About 20 species, varying in ordinary natural height from 8 to about 90 feet, have been introduced to Britain from the West Indies and the hot parts of Continental America; and several more are known. Their calyx is fleshy and coloured; their fruit is berry-like and grows in clusters; and the favourite habitat of some of the best known is the sea-board. Hence both the popular name of seaside grape, and the botanical one of coccoloba,—the latter signifying "a lobed berry." The fruit of some, though very astringent, is eaten by the natives; and the wood of the tallest and bulkiest is used as timber.

One of the smallest in size and earliest known may serve as a sufficient specimen of the whole. This grows on the sandy shores of the West Indian islands. Several stalks rise from each root, and attain a height of from 8 to 10 feet, and are garnished with foliage and clothed with a light brown smooth bark. The leaves are alternate, and stand on short footstalks, and are very thick and stiff and almost round, and have a diameter of from 5 to 7 inches, and are lucid green above and veined below. The flowers come out from the wings of the stalks in long slender bunches like those of the common currant, and have white six-parted petals, and are succeeded by purplish-red berries about the size of common grapes, each enclosing a nut of its own shape.

SEASIDE OAT. See UNIOLA.

SEASON. One of the four great natural divisions of the year,—spring, summer, autumn, and winter. In a general view, in reference to plants, spring is the season of germination; summer, of blooming; autumn, of fruiting or seeding; and winter, of repose. The natural periods and duration of any one season always differ more or less from those fixed artificially in the calendar, and sometimes differ very widely, and are far from being uniform in successive years. The stages of tillage and cultivation, therefore, ought to be regulated far more by the natural phenomena of the seasons than by their mere calendarial divisions and dates. The word season is also used to designate the whole of the active period of one year, as distinguished from the inactive period, or the whole of the period between the sowing and reaping of an annual crop as distinguished from the period of the ground being unoccupied. It is likewise used to denote the fit time of the year or the fit condition of things for the performing of any specific operation,—as the season for ploughing or for sowing,—the season for barking trees or for felling them.

SEASONING. The rendering of food relishable by the addition of some condimental substance, or the maturing of a dead organic material for use by bringing it into a suitable and permanent condition.

SEAVES. Rushes. Seavy ground is ground overgrown with rushes. But the expression is provincial, and, in a great degree, obsolete.

SEA-WALL. See EMBANKMENT.

SEA-WARE. Fuci, together with intermixed substances, found in large quantities on the sea-shore, and used by farmers and gardeners as manure. The fuci are described in the article FUCI; and one important economical purpose for which some of them were formerly employed, is noticed in the article KELP. The fuci found still attached to the rocks are often called black ware; and those found in a loose state, cast ashore after storms, are often called red ware or loose ware, or par excellence sea-ware; and both kinds bear also the popular names of sea-weed, sea-wrack, and tangles. The substances usually intermixed with them are sea-water, shells, molluscs, exuviæ, and sand.

The black ware may be cut and gathered in the same manner as in former years for kelp. It is not so easily acted on by moisture or the atmosphere as the red, and is longer in decomposing either as a top dressing or as an incorporated manure, and is not so suitable for any purposes which require promptitude and rapidity of fertilizing action; yet it may be advantageously used either in decomposing moss, or in mixing with soil to make a compost, or in reducing stable dung and bringing it to a state of fermentation, or in littering cattle during a scarcity of straw; and, in districts where it is in request at a considerable distance from the coast, or at other seasons of the year than spring or winter, it may be spread out on the shore to dry,

and then stored up in ricks or stacks in the same manner as hay, and finally carried inland, when wanted, at one-fourth or one-sixth the cost of fresh, wet ware.

The red ware—or, par excellence, sea-ware—is sometimes cast ashore in great quantities, and always comes very irregularly, and is controlled by winds, tides, and currents, and may be swept away again the very next tide after it arrives; so that it needs to be closely watched, and must be taken just when it can be got, and ought always to be promptly gathered and immediately carted or boated off. A vast trade in it is carried on by the fishermen of the rugged and sinuous coasts in the vicinity of some of the larger ports of the west of Ireland. It needs no preparation for manurial use, as it contains no woody fibre, or other stubborn principles requiring chemical reduction; and it is always most profitable when applied in as recently gathered state as possible, for it loses both bulk and fertilizing substance by exposure, drying, or fermentation.

Fresh sea-ware produces very powerful fertilizing effects, but generally does not act longer than a single season. It consists organically of cellular tissue, and contains a very large proportion of water, or of the elements of water; and, when simply exposed to the air, either on the surface of the ground, or within the upper part of the soil, it melts and mainly disappears without evolving any appreciable heat. It contains much soluble mucilage; and passes largely, by brief or rapid fermentation, into carbonic acid and watery vapour; and probably offers copious supplies of the former of these proximate principles in solution in water for absorption by the spongioles of growing plants of the field. It was formerly thought to fertilize chiefly by means of carbonic acid, and to be neither a nitrogenous manure, nor a very good saline one; but, though it certainly emits, in the process of decomposition, a very different odour from that of nitrogenous land plants, it has been ascertained, in some instances, to contain a greater proportion of nitrogen than even ordinary farm-yard manure; and, in as far at least as it is identified with the kelp-yielding fuci, it is known to excel almost all other fresh vegetable substances, bulk for bulk, in the amount of its saline principles. "Much of the fertilizing power of sea-weeds," says Dr. Shier, "is no doubt due to the large quantity of alkaline and earthly salts they contain. The proportion of alkaline salts varies considerably in different species; so much so, that kelp-burners use chiefly the firm coriaceous species that grow about and under low water-mark; such as the *Fucus digitatus, F. nodosus, F. saccharinus*, &c., while they reject or account of much less value, the *Fucus serratus, F. vesiculosus, F. canaliculatus*, and others that grow in shallower water. In the absence of accurate analyses of the inorganic part of these plants, it is not possible to speak with precision of their relative values; but on the shores of the north of Scotland, I have uniformly found that the most observant farmers, who have had much experience in the use of sea-weeds as a manure, manifest the same preferences as kelp-burners."

Sea-ware, in a fresh state, acts admirably when laid on stubbles before winter ploughing, and on leas before being ploughed for oats, and on wheat fallows before the seed-furrowing. The late Dr. Browne of Gorlstone, in Suffolk, records, that, in October, 1819, he spread 27 huge cart-loads of loose sea-ware, fresh and wet, upon little more than an acre of bean-stubble, instantly ploughed it in, and dibbled wheat upon it,—that in the same month he manured the adjoining land with 3 bushels of salt and 15 loads of farm-yard manure per acre, and on the 15th of November dibbled it with wheat,—and that, as the result of this comparative trial, the sea-weeded portion gave three times the produce of any equal part of the field.

Sea-ware is an excellent top-dressing for grass lands, under the alternate husbandry, both producing a rich covering of deep green grass, and predisposing the land very favourably for the succeeding grain crop; and when laid on the grass in either summer or autumn, it rapidly disappears, and soon becomes traceable only in its effects. Some farmers and many market-gardeners, particularly on some of the eastern sea boards of Scotland prefer sea-ware to all other manure for cabbages, borecoles, and other succulent green crops which are liable to become rank and bitter when grown after farm-yard manure. Many cottiers and small farmers, especially in Ireland, and also some large cultivators, applaud and practise the use of it in drills as a manure for potatoes; but others condemn this use of it as injurious to the mealiness and flavour of the tubers.

A grand use of sea-ware, or rather class of uses, is to treat it as a main and modifying ingredient in composts. "The quality of earthy composts and of farm-yard dung," remarks Mr. Donaldson, "is prodigiously improved by a mixture of sea-weed. In these cases, it is laid on the top of the heaps before they are turned over, and a bottom of loose friable earth is generally provided to absorb the oozings of the mixture. Sea-weed is very profitably used in mixing the farm-yard dung in the yards in thin layers alternately with straw; and manure of a most excellent quality has been produced by this method. During the seasons of sea-weed coming on the shore, the farmers have heaps of dung or soil in readiness to receive the immediate benefit of the wrack; and these heaps, along with any lands that may be in a state fit to receive it, afford a ready application of this invaluable article. Farm-yard dung for turnips is improved by it almost beyond description; moisture is imparted, the straw is decomposed, and the whole mass is converted into a juicy mucilaginous state,

and never fails to vindicate the expectations of its effects."

SEA-WATER. The water of the ocean and of its inlets. A specimen of it analysed by Marcet contained 2·666 per cent. of chloride of sodium, 0·466 of sulphate of soda, 0·1232 of chloride of potassium, 0·5152 of chloride of magnesium, and 0·0153 of sulphate of lime; and a specimen from the North Sea, analysed by M'Clemm, contained 2·484 per cent. of chloride of sodium, 0·135 of chloride of potassium, 0·242 of chloride of magnesium, 0·12 of sulphate of lime, and 0·206 of sulphate of magnesia. Sea-water, as a comparison of these two analyses may suggest, varies somewhat widely in constituency in different latitudes and in different seas; it also varies, in any one sea near the coast, in rainy and in dry seasons, or within or without the sweep of fresh-water currents from rivers; and, in addition to its main saline constituents mentioned in the two analyses which we have quoted, it usually contains very minute or inappreciable quantities of ammonia, carbonic acid, silica, magnesia, iron, manganese, sulphuretted hydrogen, organic matter, carbonate of lime, phosphate of lime, and iodides and bromides. It has a specific gravity of from 1·0269 to 1·0285; and is heavier in the higher latitudes of the torrid zone than at the equator. It owes its saline taste to its chlorides and sulphates,—and chiefly to its chloride of sodium; and it owes its nauseousness to the combination of these with its small quantity of organic matter.

The continual evaporation of the ocean, aided by the action of winds, sends a supply of the salts of sea-water over the whole surface of the world, and constantly contributes them, through the medium of rain, for the enriching of soils, and for the nutrition of all salt-loving plants. The air hanging over any part of the sea always contains enough of common salt to make a solution of nitrate of silver turbid; and the leaves of plants growing to windward of sea-storms, even at the distance of from 20 to 30 miles from the shore, are sometimes covered with crystals of salt. Mere ordinary evaporation from the ocean, therefore, and especially a prevalence of sea-breeze in any stated direction, must be always an appreciable and sometimes a highly valuable source of the chlorides of sodium, potassium, and magnesium, and the sulphates of lime and soda and magnesia to the plants of the garden and the farm. Though the carbonate of lime in sea-water amounts to less than a twelve-thousandth part of the water's weight, it affords the incalculable myriads of corals and marine molluscs a sufficient supply for the construction of their habitations; and though the iodine in sea-water amounts to less than one-millionth of the water's weight, it is everywhere readily enough collected, absorbed, and assimilated by the Fucoideæ which require it as an aliment; so that if the quantity of salts evaporated from the ocean, and distributed by wind and rain throughout the world, were vastly less than it is, it could not fail to exert an appreciable and constant influence on vegetation. The comparative saline wealth or poverty of any piece of land, therefore, must materially depend on its distance from the ocean, or on the degree in which it is swept and watered by breezes and exhalations and rains from the sea.

Sea-water is sometimes used for saturating dung-heaps and fold-yards, at short intervals during dry weather, in places upon the coast where it can be obtained and applied at a trifling expense of labour. But the main or only useful purpose which it can serve in this way is to impregnate the heaps with its saline principles; and either this purpose may be quite unnecessary on account of the heaps themselves or the soil to which they are to be applied already containing a sufficient quantity of these principles, or it may be more facilely and cheaply accomplished by means of a sprinkling of bathing salt. A farmer should consider, also, whether his dung-heaps may not get more injury from the excessive moisture of the saturations than they can get good from the impregnations of saline principles. See the article Salt (Common).

SEA-WRACK. See Sea-Ware and Fuci.

SEA-WRACKGRASS. See Wrackgrass.

SEBÆA. A genus of ornamental, exotic, annual plants, of the gentian family. Five species, all late-bloomers and only a few inches in height, have been introduced to Britain, from Australia and Southern and Western Africa; and they require greenhouse treatment, and have severally white, yellow, brown, and red flowers.

SEBESTEN PLUMS. See Cordia.

SECALE. See Rye.

SECAMONE. A genus of exotic, evergreen, twining plants, of the swallow-wort tribe. The emetic species, *S. emetica*, possesses medicinal properties. It has a height of 6 or 7 feet, and carries white flowers, and was introduced to British collections about 32 years ago from India.

SECHIUM. See Choko.

SECRETION. The function by which a living organ selects and separates certain principles from the fluids which pass through it or upon it; also, the amassment of the principles which this function selects and separates, or the substance into which they are transmuted in their separated state. Secretion, in the former sense, either assimilates or expels,—either appropriates the separated principles as part of the living body to which the organ belongs, or drives them into a course of being rejected from it on account of their unfitness for its nutrition; and a secretion, in the sense of the principles themselves, is a proper or recremental secretion when destined to assimilation, and an excremental secretion or an excrement when destined to expulsion. The secreting organs, in both animals and plants, are principally glands, cells, membranes, and infinitesimal tubes.

SECURINEGA. See Otaheite Myrtle.

SEDATIVE. A medicine which diminishes irritability and represses spasmodic action. Narcotics are sedatives, but exert first a stimulating influence; and both these sedatives and others require to be used with caution, and are far too mighty agents to be handled by empirics and quacks.

SEDGE. See Carex.

SEDUM. A genus of ornamental plants, of the crassulaceous order. It has a very near relationship to the houseleek genus. Fourteen species of it grow wild in Britain; 50 species or upwards have been introduced from other countries; and nearly 30 more are known. All the species in Britain, except two or three, are hardy; and the great majority are perennial evergreen herbs. The leaves of almost all are alternate, fleshy, very succulent, and either flat, tumid, or cylindrical; and the flowers of most grow in cymes, and are either yellow, white, reddish, or purplish. Nearly all love a sandy loam; and all, except a few annuals and biennials, are propagated by division of the plant. Some of the indigenous species are sometimes called houseleeks; but the greater number are more commonly called stonecrops; and one of the best known is called Orpine, and has been described by us under that name. All the indigenous species are perennials.

The thick-leaved sedum, *S. dasyphyllum*, grows on old walls in England, and has a height of only 2 or 3 inches, and carries white flowers in June and July.—The six-angled sedum, *S. sexangulare*, also grows on old walls in England, and has twice the height of the preceding, and carries yellow flowers in June and July.—The glaucous sedum, *S. glaucum*, grows on barren sands in some parts of England, and has a height of only 2 or 3 inches, and carries yellow flowers in July and August.—The whitish-leaved sedum, *S. albescens*, also grows on barren sands in England, but is more rare than the preceding, and has a height of 5 or 6 inches, and carries yellow flowers in June and July.—The taper-leaved sedum, *S. teretifolium*, is a rare indigen of some parts of Herefordshire, and has white flowers and a creeping habit.—The rock sedum, *S. rupestre*, inhabits the rocks of various parts of England, and has a height of 2 or 3 inches, and carries yellow flowers in July and August.—The white sedum, *S. album*, also inhabits the rocks of England, and has a similar height to the preceding, and carries white flowers in June and July. A small flowered variety of it, with a trailing habit, *S. a. micranthum*, occurs in Gloucestershire.—Forster's sedum, *S. Forsterianum*, inhabits the rocks of some parts of Wales, and has a height of 2 or 3 inches, and carries yellow flowers in July and August.—The reflex-leaved sedum, *S. reflexum*, inhabits old walls in England and Scotland, and has a height of about a foot, and carries yellow flowers in June and July.—The acrid sedum, *S. acre*, also inhabits the walls of Britain, but has a height of only 2 or 3 inches, and carries yellow flowers in June.—A dwarfish variety of it, *S. a. diminutum*, occurs on some of the heaths of England; and a long-shooted variety, *S. a. elongatum*, is found in Suffolk.—The villous sedum, *S. villosum*, inhabits moist situations on the lofty mountains of England and Scotland, and has a height of 5 or 6 inches, and carries pink flowers in June and July.—The oblong sedum, *S. oblongum*, inhabits the rocks of Britain, and is very dwarfish or only an inch or two high, and carries white flowers in July and August.—The English sedum, *S. anglicum*, also inhabits the rocks of Britain, and is similar in height and bloom to the preceding; and a distinct variety of it called the Irish, *S. a. hibernicum*, occurs in Ireland, and comes into flower so early as June, and continues in bloom till August. A small-leaved and early blooming variety, *S. a. microphyllum*, occurs also in Britain.

SEED. The reproductive epitome of a phænogamous plant. It is the grand provision for continuing and multiplying vegetable species; and presents a considerable analogy in the vascular classes of the vegetable kingdom to an egg in the oviparous classes of the animal kingdom. Some chief things respecting the constitution of a seed have been stated in the articles Ovule, Cotyledon, and Albumen; respecting the uses of many seeds for food and for economical purposes, in the articles Alimentary Principles, Food of Animals, Oil, Oil-Cake, Linseed, Organic Chemistry, and some others; respecting defects and losses of artificially sown seeds, the saving of corn-seeds, and the management of hybrid seeds, in the article Agricultural Seeds; respecting the chemical changes which take place in the sprouting and growth of seeds, in the articles Germination and Malt; respecting the envelopes and the processes of ripening, in the articles Pericarp and Fruit; respecting the proper artificial depositing of seeds for growth, in the article Sowing; and respecting the species, properties, uses, and treatment of all the chief economical seeds, in the articles on the respective plants to which they belong, such as Wheat, Barley, Oat, Pea, Bean, and multitudes of others. We shall, in the present article, therefore, do no more than make a few descriptive statements respecting seeds in general, and add some important practical remarks respecting the principal species of seeds employed in agriculture.

Every seed, whether monocotyledonous, dicotyledonous, or polycotyledonous, contains the embryo or rudiment of a future plant, and comprises an ample and most beautiful provision for its protection during dormancy, and for arousing and feeding it at the time of germination. The foramen of the ovule or seed-vessel of the flower closes at the introduction of the pollen; the integument afterwards hardens; the juicy or pulpy contents increase and consolidate; nour-

ishment is conveyed through a placental canal; and the seed, or the fruit which contains it, when fully formed and in possession of all the organism and substance requisite for independent existence and subsequent reproduction, drops from the placental attachment, and therefore from the plant, and ever after retains a scar or hilum at the point where the attachment existed.

The forms, surfaces, and composition of seeds themselves, and of the carpel envelopes which enclose them, are exceedingly diversified, and exhibit the most minute and comprehensive adaptation to the nature and habitats of their respective plants, and afford thousands of most exquisite displays of the wisdom and goodness of the Creator. All have an organization and a constitution exactly suited to their own reproductiveness, and most, at the same time, have a prolificity and consistence and composition expressly adapted to serve as food or medicine to all the higher orders of animals; while some, in one and the same process, contribute their pericarps to the feeding of animals, and acquire preparation and excitement for their own office of reproduction. Starch, sugar, gum, oil, proteinaceous principles, alkaloids, and multitudes of peculiar compounds, are so wonderfully diversified in the different species, too, as, in all the endless diversities of climate, soil, form, and habit, to achieve most nicely the purposes of maintaining vitality, resisting injurious attacks of insects, and making preparation, by chemical change and progress, for both the extraneous office of affording food to animals and the intrinsic function of developing the embryo of the future plant. Coverings of amazing variety of kind, and all perfect and beautiful, protect the interior substance and organisms from the injurious effects of excessive heat or cold, or of undue dryness or moisture; and many of these, at the same time, constitute either food to animals or nourishment to the germinating seeds. See the articles Fruit and Pericarp. The contrivances for dispersing seeds, too, so that the plants which arise from them may find fresh soil to nourish them and ample space to grow in, are numerous and admirable. "Not only are the winds and the waters and animals put in requisition, and unconsciously employed in the operation of sowing and planting, but the seeds themselves are endowed in many cases with certain mechanical properties which aid their dispersion. Thus the awn of an ear of barley is so sensible to moisture, that it lengthens in damp and shortens in dry weather; and by this alternate extension and contraction, aided by the short and thick set prickles by which it is serried, it will in the course of a few mornings drag away the seed to which it is attached to some distance from its parent stalk. Thus, again, the seeds of the thistle and dandelion have a species of downy wings attached to them, by means of which they float through the air, and are carried by the wind to great lengths. And thus, too, the pods of the broom and furze are furnished with an elastic spring, which, on being acted on by the heat, forcibly ejects the seed, and with a considerable report, to a distance from the spot. 'Who,' says Sir J. E. Smith, 'has not listened in a calm and sunny day to the crackling of furze bushes, caused by the explosion of these little elastic pods, or watched the down of innumerable seeds floating on the summer breeze, till they are overtaken by a shower, which, moistening their wings, stops their further flight, and at the same time accomplishes its final purpose by immediately promoting the germination of each seed in the moist earth? How little are children aware as they blow away the seeds of the dandelion, or stick burs in sport upon each other's clothes, that they are fulfilling one of the great ends in nature?' The ocean itself serves to waft the larger kinds of seeds from their native soil to far distant shores. While in ordinary cases, also, plants drop and disperse their seeds in dry weather only,—which is just the kind of weather most favourable to its success, for the seed, according to the farmer's adage, 'loves a dry bed,'—there are some plants, natives of arid deserts, which act according to a different economy. Thus, the cup of one plant of the desert has springs to close in dry weather, and to open only in the coming of moisture. Thus, also, the seed-vessel of the rose of Jericho is rolled by the winds along the wilderness until it meets with a moist spot, and then, but not till then, it opens and parts with its seed. How wonderful all this arrangement and contrivance! Here is not the foot print of blind chance, but the finger of God."

Seeds which have lost their vitality through age or bad keeping are sometimes doctored by chemical appliances, and brought into the market under the name and with the appearance of perfectly fresh seeds. A report upon enquiries into adulterations by a Committee of the House of Commons, a good number of years ago, stated that the "old seed of white clover was doctored by first wetting it slightly, and then drying it with fumes of burning sulphur, and that red clover-seed had its colour improved by shaking it in a sack with a small quantity of indigo; but this being detected after a time, the doctors then used a preparation of logwood, fined by a little copperas, and sometimes by verdigris, — thus at once improving the appearance of the old seed, and diminishing, if not destroying, its vegetative power, already enfeebled by age. Supposing that no injury had resulted to good seed so prepared, it was proved that, from the improved appearance, its market price would be enhanced by this process from 5s. to 25s. a hundred weight. But the greatest evil arose from the circumstance of these processes rendering old and worthless seed equal in appearance to the best. One wit-

ness tried some doctored seed, and found that not above 1 in 100 grew, and that those which did vegetate died away afterwards; whilst about 80 or 90 per cent. of good seed usually grows. The seed so treated was sold to retail dealers in the country, who of course endeavoured to purchase at the cheapest rate, and from them got into the hands of the farmers,—neither of these classes being at all capable of distinguishing the fraudulent from the genuine seed. Many cultivators in consequence diminished the consumption of the article; and others were obliged to pay a higher price to those who had skill to distinguish the mixed seed, and who had integrity and character to prevent them from dealing in it." Similar infamous adulterations, no doubt, are occasionally practised on other seeds; and as constitutional defects and diminutions of vigour and losses of vitality also occur from the operation of natural causes and from inadvertencies in treatment, farmers and gardeners ought never to risk a crop upon the sowing of seeds about which there can be the slightest doubt till they have first put them to the test. The colour of seeds, though a popular mark of goodness, is a very misleading one, and ought to be appreciated, never as any index whatever of vitality or vigour or other intrinsic properties, but merely as an adventitious enhancer of market value. The figure of a seed, in a certain degree, is a fixed character of species or variety, and yet, to a considerable extent, is determined by soil and climate,—insomuch that comparative sphericity is promoted by warm and early situations, and comparative elongation by cold and late ones. Large size, too, is generally owing to the soil,—yet is likewise a sign of ripeness. All seeds of home-growth set apart for sowing ought to be the ripest individuals of the most vigorous plants, and may easily be obtained free from admixture with the less ripe ones simply by slightly beating or lightly thrashing the plants.

Annual or biennial farm plants, when cropped through a series of times from seed grown on one field or on fields of one character as to soil and situation, are liable to degenerate somewhat analogously to domesticated animals who are bred in-and-in; and they experience corresponding invigoration from renewals of seed either by importation or by hybridizement. "Where domestic seed is relied on, it is proper to change the seed from the heavier to the lighter parts of the farm, and *vice versa*, if there be much difference. On clay farms, in general, domestic seed may be safely used for some time; but with a view to prevent degeneracy, it is an excellent practice to select from the growing crops the ears which are the soonest ripe, and which are of the plumpest quality; by this means, those husbandmen who devote themselves in a peculiar manner to this object can not only supply themselves, but can always command a much higher price than others, by selling the grain raised upon their farms for seed, either among their neighbours, or to be sent to other districts. A change of seed is in general to be recommended, as founded on rational principles. Every species of grain has a climate adapted to it, where it flourishes, where it grows to perfection, and where it never degenerates. In a country where wheat grows naturally, as in Sicily, seed dropping from the mother plant arrives at perfection, though neither the seed nor the soil be changed; but as wheat is not a native of Britain, it has here a great tendency to degenerate, more especially in the more northern districts,—and it degenerates rapidly if the seed be sown, year after year, where it was produced. Nor is it sufficient that the seed be taken from a different field; it ought also to be taken from a different soil, and from a different atmosphere. Farmers on the borders of Lincolnshire make a considerable advantage by purchasing their seed wheat from the Fens; and they find the change useful, and at the same time save in the price. In Flanders, they never use the grain or seeds grown on the lands to be sown, nor regard the additional expense attendant on the purchase of seed that is heavier and more healthy; their flax seed they bring from Riga or Memel, and their potatoes from Brabant. The Farming Society of Ireland, by its premiums, introduced the habit of sowing seed imported from England; and by this means the quality of the Irish grain is greatly improved, and the samples of corn now produced for sale at the Irish, would not disgrace any English market. Besides preventing a degeneracy in the quality of the grain, the crops of the farmer, by a judicious change of seed, will sooner reach maturity,—an object in many cases of the greatest moment. English grain, sown in Ireland, generally comes to maturity ten days, or even a fortnight, earlier than the native seed under similar circumstances. It is well known that a change of constitution in plants, originating from the situation in which they have been placed, is commonly transmitted to their offspring. Plants propagated from seed, produced in a warm sandy soil, will therefore grow fast in whatever soil the seed is sown; and plants from seed produced in a cold stiff soil, are late of growing, even in a warm soil. Hence the advantage of changing seed from a warm to a cold soil; for though seed from a warm soil will not grow so quickly in a cold soil as in a warm soil, it will, however, always grow more quickly than seed from a cold soil. The quantity also will be increased. From an experiment made by the celebrated Lord Kames, it would appear that the produce of changed seed exceeds that of old seed, at the rate of nearly 26 per cent. The farmer, however, ought not to alter his seed while it gives him fair and reasonable satisfaction, unless he has every reason to be convinced that better can be obtained by a change. It is proper to add, that in two cases it has been found expedient to change the seed from an inferior to a superior

climate. In Flanders, where great quantities of flax are grown, the seed must be brought from the Baltic; otherwise the crop will be deficient. In the case of potatoes, also, seed is imported from an inferior climate, as the most likely means of preventing the disease called the curl. Besides changing seed, crossing different varieties has been found of use. Mr. Knight not only raised new varieties of apples, and of the garden pea, but likewise tried experiments with crossing wheat, which he effected by sowing the different kinds together. This was attended with a most extraordinary result; for when, in the year 1796, almost the whole crops of corn in the island were blighted, the varieties obtained by crossing alone escaped, though sown in different soils and in very different situations."

The quantity of any kind of agricultural or horticultural seed sown ought to be controlled by considerations respecting the climate, the soil, the season, the weather, the mode of sowing, and the quality of the seed. In a climate of comparative unsteadiness and severity, which is liable to a succession of variable weather, or which is occasionally swept with great storms of rain or snow, or which is sometimes visited with unseasonable frosts or with great and sudden changes of temperature, a larger quantity of seed is requisite, were it merely to provide against accidental injuries and killings of the seed itself or of the young plants rising from it, than in a climate of comparative repose and mildness. On thin light soils, which are favourable to tillering, and yet contain comparatively little sustenance for plants, and are unable to produce very luxuriant crops, considerably less seed is proper than on strong, stiff, retentive soils, which are unfavourable to tillering, and yet contain comparatively large stores of nourishment, and are well able to support the most abundant crops. But when even strong clay lands have been thoroughly under-drained, and are in high condition, and have been rendered friable and mellow by assiduous tillage and fallowing, they require as little seed as light lands, and sometimes even less. Though a sparcely sown crop of wheat, on such soils, may appear thin during winter, the seedling plants have time and vigour enough to fill up the field by means of tillering, and will be found to produce a full crop in autumn. When sown too thick, rich fields are apt to become overstocked with more plants than can come to perfection; and these accordingly grow up weak, slender, and unproductive. Less seed is required by summer fallowed land than by bean stubble, and less by bean stubble than by clover lea, and less by clover lea than by turnip land sown in spring. Seed sown at a comparatively remote period from the time of ripening gives the crop more scope for tillering and ampler power to overcome retardations and resistances from adverse weather, than seed sown at a later period, and therefore ought to be correspondingly less in quantity. When the season is very dry, and occasions great paucity of moisture in the soil at the time of sowing, more seed may fail to vegetate than in other circumstances, and therefore proportionally more ought to be sown. Less seed is proper in the dibbling method of sowing than in the drill method, less in the drill method than in the broadcast method, and very much less in commixation with another seed for an accompanying crop than when sown alone and intended to occupy the whole ground. Less quantity, too, is required of perfectly sound seed than of merely mediumly good seed, less of mediumly good seed than of very doubtful or decidedly bad seed, less of round, plump, large seed than of longish, slender, and comparatively bad seed, and less of seed which is well fortified by preparatory processes for resisting the attacks of insects and fungi and unfavourable weather than of seed of the same quality which is either not at all or very inadequately fortified by such processes. See the article Sowing.

The preparing of seeds comprises processes for detecting and separating unsound grains,—processes for accelerating germination or promoting earliness of growth after sowing,—processes for protecting the seeds against the attacks of vermin, grubs, and parasites,—and processes for augmenting the nutrimental resources of the seeds, and enabling them either to dispense, in some degree, with the aid of manures in the soil, or to use up the manures with a more luxuriant and productive account. One of the simplest of these processes is noticed in the article Brining; and some of the most peculiar are mentioned in the articles on the several plants or crops to which they apply.

The detecting and separating of unsound grains can, in most instances, be readily accomplished by merely pouring the seeds gently into common water or into a weak solution of salt and water, —and, if necessary, slightly stirring the water or solution till all the grains have an opportunity of becoming immersed or wetted; for the sound grains will sink to the bottom and remain there, and the unsound ones will either swim from the first on the surface or will readily rise with aslight stirring, and may easily be skimmed off.

The accelerating of the germination of seeds is generally effected by artificial applications of heat and moisture during some hours or days immediately before the intended time of sowing. A common method is simply to steep the larger and clean-skinned seeds, such as beans and barley, in pure water, and to immerse the smaller and rougher seeds, such as those of carrots, in a little well-moistened soil, and to keep it in a warmish place, and turn it occasionally over. But all such processes, especially in the case of the former class of seeds, require to be conducted with judgment and caution and a wise regard to time and temperature; for, if otherwise conducted,

they may either enfeeble the seeds or absolutely destroy their enclosed embryos.

The preserving of seeds from the attacks of insects, field-mice, birds, and other depredators, is effected principally by steeps or other applications of whale oil, stale urine, or any other substance which, while not injuring the seeds, will long continue to emit an offensive odour. The Romans of ancient times used, for this purpose, the lees of oil, decoctions of cypress leaves, the juice of house-leeks, and some similar substances; and the British and Continental farmers of the present day, in the case at least of wheat and barley and oat seeds, extensively use saline and caustic applications.

The enriching of seeds with such coatings or saturations as shall produce similar effects to doses of suitable manure, is effected, in some instances, by processes which, at the same time, protect the seeds from grubs and fungi and unfavourable atmospheric influences. "Public attention," remarked Professor Johnston in 1844, "has lately been drawn in this country to the possibility of so manuring or otherwise doctoring the seeds of our usual grain crops, before they are put into the ground, as to do away with the necessity of manuring the soil itself. It has been long known to practical farmers that, by steeping their seeds in urine, in salt and water, or in other solutions, and sprinkling them while wet with quicklime, their growth is in many cases promoted, and the rust, smut, and similar diseases, in a great degree prevented. It has been observed also in regard to potatoes, that in some soils a dusting of lime makes the cuttings more productive than they would otherwise be, and that, when powdered with gypsum, they thrive still better. The absolute effect indeed of all such applications to the seed corn or to potatoes, will in every case be modified by the kind of soil in which the seed is sown. If the soil abound in common salt, the salting of the seed will be less efficacious, while if it be rich in lime or in gypsum, the dusting of the potatoes with these substances will produce a less striking effect. Yet the above observations of practical men show that it is possible in certain circumstances, and by the use of certain substances, so to doctor or manure the seed we intend to sow, as to make the growth of our crop more sure, and the return of our harvests more abundant."

Some remarkable results, in this way, have already been obtained. Mr. Dalziell of Holm of Drumlanrig, four or five years ago, steeped seed-barley in diluted sulphuric acid, and found the crop from it better in all the stages of growth, and productive of eight bushels of grain more per acre, than a corresponding crop from unsteeped seed. Tinzmann of Silesia, according to a report of experiments made to a meeting of agriculturists at Munich in 1844, found that the steeping of seed-barley, during six hours, in a dilution of sulphuric or muriatic acid, at the rate of about 5 lb. of acid per acre in 40 times its own weight of water, gave one-fourth more straw and grain than unsteeped seed,—that a similar dilution and quantity of acid sprinkled over the ground before sowing, gave very little increase,—that steeping in pure water gave more straw than unsteeped seed, but a very slight increase of grain,—and that the steeping of wheat-seed, oat-seed, vetch-seed, turnip-seed, and grass-seeds in a dilution of muriatic but especially of sulphuric acid, gave more or less increase,—but that the acid must be used with caution, and sometimes diluted to a greater degree than in 40 times its weight of water, and that the success of the steeping is greatest in soils which have long been in good cultivation, and may not always be observable on poor exhausted soils. Mr. James Campbell of Dundee, according to a communication which he made to the Highland Society in 1843, found that extraordinary vigour and productiveness in corn and herbage plants were obtained by steeping their seeds in single or mixed solutions of nitrate of soda, nitrate of potash, nitrate of ammonia, muriate of ammonia, and sulphate of ammonia,—that the various mixtures should consist of the salts exactly neutralized, and dissolved, in from 8 to 12 measures of water,—and that the duration of the steeping did best at from 8 to 10 hours with clover seeds, from 16 to 20 hours with gramineous seeds, and from 50 to 90 hours with corn seeds, yet not more than 60 with barley seeds; and he afterwards offered his preparations, under the name of "corn-growing liquids," for sale, and received considerable corroboration of the published results of his experiments from careful trials on the part of some distinguished agriculturists. M. Victor of Neiderholm, in Hesse Darmstadt, according to a pamphlet published by him in 1843, found, from experiments conducted during five years, that corn plants acquired extraordinary vigour and productiveness, and at the same time escaped rust and other diseases, in consequence of first immersing the seeds in a semi-fluid mass of blood, oil, salt or sal ammoniac, powdered clay, linseed meal and water, and then so spreading them upon drying mixtures as to cause them to be coated with the preparation. Another German experimentalist, Franz Heinrich Bickes, published in the same year a professed discovery of a method of so steeping or otherwise preparing all sorts of field and garden seeds as to cultivate the soil without the aid of manure; and many other persons of late years, in Britain but especially in Germany, have thought, in various ways, of fertilizing soils or invigorating crops by means of steeping seeds.

Unhappily, most of the advocates of the new theory drive it to the length of extravagance or absurdity; and are not content to regard their respective methods of preparing seeds as simple or even important aids to fertility, but insist on their being complete substitutes for all manure, or even agencies of far superior power to

the combined action of both soil and manure. Mr. Campbell, for example, says, "From the experiments which I have already tried, I am quite satisfied that, even without the application of common manures, double crops at least may thus be raised, and under the application of the ordinary manures crops tenfold greater than usual;" and Mr. Bickes says, "The discovery of cultivating the soil without manure has been carefully verified in different countries and in the most dissimilar soils. It is not the discovery of a mere crude substitute for manure, but rests on a knowledge of the nature of plants, by which the vital power is increased in all respects, and their existence elevated and ennobled. Who can assign limits to the growth of a plant? I possess dried plants of wheat, consisting of 56 and 57 stalks; Indian corn, grown in a poor soil, with 3 or 4 stems and 8 or 9 heads; sunflowers 11 feet high, with flower disks 14 inches in diameter, and seeds as large as small coffee beans; potatoes above 7 feet high, and tubers in proportion. Drift sands have produced crops equal in quality to the neighbouring loams. Agriculture can now be prosecuted after an entirely new method. Manured every year almost without cost, plants will develope themselves almost spontaneously, and yield the largest returns." Wild assertions like these do enormous harm by deterring cautious ill-informed farmers from listening to the theories and speculations of scientific agriculturists, and by inducing sanguine, unreflecting, would-be-learned ones to waste their time and money in quixotic experiments, to the neglect of sober methods of improvement; and though they have, in the present instance, attracted great attention and drawn out a large degree of both blind opposition and credulous confidence, and though too they suggest enough of truth to point out new and very promising methods of investigation, they are, at the same time, so recklessly absurd as to deserve no small measure of pity or contempt. A plant can no more grow without food in the soil than a foal or an infant can grow without food received into the stomach; and a seed cannot possibly acquire any increase of its functional powers except by means which shall either protect it from morbific or debilitating influences, or enrich it with additions to its intrinsic stores of nourishment, or excite and strengthen it to take up additional supplies of food either from the soil and the atmosphere or from artificial deposits of manure.

The real conditions under which seeds can be fertilizingly benefited by any doctoring processes, and the true principles on which the invention of the best of such processes should be attempted, were well-stated, in the following terms, in 1846, by Professor Johnston: "When barley is steeped for the purpose of malting, the water, which is several times renewed, extracts from it a considerable proportion both of organic and of inorganic matter. The inorganic part of the extract is rich in alkaline matter and in phosphates, all of which must be lost to the seed, and yet it sprouts well in the hands of the malster notwithstanding. Is the saline matter which the grain thus loses necessary to its healthy or perfect condition? Is it necessary to its growth in ordinary soils? Is it a provision of nature by which a store of these substances is laid up in the seed above what is required for its own perfect development, with the view of meeting the emergency of its being placed in a soil in which these substances are unusually deficient? Or are we to consider as only accidentally present the saline and other compounds which are thus easily extracted from it by simple steeping in water? These are interesting questions, especially to the chemical physiologist; and it would be very interesting to solve them. If the seeds sprout and the plants grow as well, and yield as good a crop on all soils, after these salts are extracted by water, as when the unsteeped seed is sown, or seed steeped only in so much water as it can absorb, then we may infer that what the water extracts is not necessary, and that the seed would perform all its natural functions as well without their presence. In that case we should be justified in concluding that they formed no part of the necessary and natural constitution of a healthy seed.—But if, on the other hand, the seed thus exhausted by water grows less vigorously and yields a small return, then we should be justified in concluding, not only that these saline matters which water extracts are really necessary to the perfection of the seed, but in inquiring whether the seed might not with advantage be provided with a larger portion—be beneficially steeped, that is, in a solution which would still further charge it with these saline substances, before it was committed to the soil. The answer to this inquiry would be obtained by steeping the grain in a solution containing the same or similar substances to those naturally present in the perfect seed. Such a steep would be obtained by the use of a mixture consisting of phosphate of soda, sulphate of magnesia, nitrate of potash, common salt, and sulphate of ammonia. One pound of each of these substances dissolved in 10 gallons of water, will be sufficient to steep 300 lbs. of seed, which may remain in the solution from 30 to 50 hours, and should be afterwards dried with gypsum or quick lime. The quantity of saline matter above prescribed is sufficient to impregnate the grain with an additional portion equal to that which it naturally contains.—It is possible that after the grain has been extracted by water, it may again be impregnated beneficially with an artificial saline solution, such as that above described, or by a solution of one of the substances only of which the mixture is composed—of nitrate or phosphate of soda, for example, or of sulphate of soda. Most of these experiments bear more or less directly upon practical opera

tions, but they are especially interesting to the physiologist. I would, therefore, venture to suggest that advantage might be derived, and considerable knowledge obtained, by the careful performance of such a series of experiments as the following upon the steeping of barley:—Seed steeped and washed in repeated waters; steeped in as much water only as it can absorb; steeped in diluted sulphuric acid; steeped in diluted muriatic acid; steeped in mixed saline solutions as above; steeped first in water and then again in the mixed saline solution; steeped in nitrate or phosphate of soda; steeped first in water and then in nitrate or phosphate of soda."

SEED-BASKET. See Rusky.

SEED-CORN. See Agricultural Seeds.

SEEDLING. A young plant which has not been removed from the seed-bed; also a plant of any given species raised from seed, as distinguished from one raised in any of the methods which do not originate varieties, or which do not renovate an old stock.

SEED-LIP. A basket in which a sower carries seed-corn during the process of broadcast field sowing.

SEED-SIFTER. See Sieve.

SEEL. The season or suitable time for any agricultural operation. Barley-seel, for example, is the season for sowing barley; hay-seel is the season of hay-making; and bark-seel is the season for barking trees. But the word, in all its uses, is provincial.

SEELING. The commencement of the appearance of white hair in a horse's eye-brows. This usually occurs between the 14th and the 16th year of a horse's age, and is therefore a mark of his becoming old.

SEG. A castrated bull. The word is provincial.

SEGGING. See Oat.

SEGS. The provincial name of sedges or carices. See the article Carex.

SELAGO. A genus of ornamental greenhouse plants, of the verbena family. About 20 species have been introduced to Britain from South Africa; and about as many more are known. Most of the introduced species are evergreen undershrubs of from 8 or 10 inches to 3 feet in height, carrying either white, blue, violet, or purple flowers, and propagable from cuttings; and all love a soil of peaty loam.

SELF-HEAL,—botanically *Prunella*. A genus of hardy herbaceous plants, of the labiate order. One species grows wild in Britain; and 12 or 13 species,—chiefly annual-stemmed perennials, of about 6 inches in height, carrying white or yellow or pink or blue or purple flowers in the latter part of summer and the early part of autumn—have been introduced from Continental Europe and North America. Most love a soil of peaty loam, and are propagated by division of the roots.

The indigenous or common self-heal, *Prunella vulgaris*, is the most interesting species, and may serve as a sufficient specimen of the whole genus. It inhabits the meadows and pastures of most parts of Britain, and is frequently found among clover. Its root is fibrous; several quadrangular, leafy stems rise from each root, and commonly attain a height of from 5 to 9 inches; the leaves are stalked and opposite, and have a brownish colour, and are entire, ovate-oblong, and about $1\frac{1}{2}$ inch long and $\frac{3}{4}$ of an inch broad; and the flowers are numerous, and grow in dense, solitary, erect, whorled spikes, and have either a white, a blue, or a purplish colour, and bloom in July and August. Two ornamental varieties, the one red-flowered and handsome, and the other double-flowered and curious, occur in gardens. This plant was formerly in repute as a vulnerary herb, and for the cure of a disease in the jaws and throat; but it has not now any recognised place in the materia medica. It somewhat readily finds its way among clover in consequence of its seeds ripening at the same time as those of that plant, and considerably resembling them; yet the seeds of self-seal may quite easily be distinguished by any ordinary observer from their being rather larger than clover-seeds and kidney-shaped.

SELENIUM. An elementary substance of an intermediate character between the metals and the simple non-metallic bodies. It is very scarce, and occurs for the most part in combination with sulphur. It is a brittle, opaque, tasteless, odourless body, of metallic lustre and lead-like appearance; but assumes a deep red colour when reduced to powder, softens into remarkable tenacity at a temperature of 212°, melts at a little higher temperature, and boils and evaporates with high yellow-coloured vapour at 650°. It greatly resembles sulphur in many of its properties and in the general character of its affinities or combinations. Some of the chief compounds of it are oxide of selenium, selenious acid, selenic acid, and seleniuretted hydrogen.

SELINUM. See Milk-Parsley.

SELLANDERS. See Mallenders and Sallenders.

SEMBRADOR. One of the earliest invented drill-sowing machines. It was invented by the Spaniard Don Joseph de Lucatello, and brought early to the notice of Britons through the Philosophical Transactions. It was fastened to the tail of the plough, and it dropped the seeds of corn-crops regularly into the furrow, and effected the sowing of any given area with about one-fifth of the seeds which were usually employed in hand-sowing; but it was not found to answer in common practice, and is now on record as a mere agricultural curiosity. See the article Sowing-Machines.

SEMICARPUS. See Cashew-Nut.

SEMINARY. A piece of ground allotted for raising perennial plants from seed, and keeping them till they become fit for removal into the

nursery or the garden. The word, as all Britons know, is also used metaphorically in the sense of a school.—the seed-bed of knowledge.

SEMPERVIVUM. See HOUSELEEK.

SENEBIERA. See WART-CRESS.

SENECILLIS. A small genus of ornamental herbaceous plants, of the jacobea division of the composite order. It comprises a yellow-flowered, annual-stemmed, hardy species, *S. glauca*,—and a purple-flowered, evergreen, slightly tender species, *S. purpurata*,—which Linnæus classed as cinerarias.

SENECIO. See GROUNDSEL.

SENEKA-ROOT. See MILKWORT.

SENNA. A well-known cathartic, consisting of the leaves of any one or two of several species of cassia. The most common senna plant is *Cassia italica*,—often called, by way of eminence, *Cassia senna*. This is a native of Upper Egypt, Nubia, and Benou; and furnishes a large portion of the senna of commerce. Its root is annual, its stem is erect, branching, and about two feet high; its leaves are pinnate, and comprise each five or six pairs of sessile, oval, pointed, yellowish-green leaflets, each scarcely an inch long, and rather more than a fourth of an inch broad; its flowers are produced in loose auxiliary spikes, and have a yellow colour, and bloom in June and July; and its legumes are ovate, kidney-shaped, membranous, leafy, and compressed, each having six or nine cells and containing the same number of oblong heart-shaped seeds. Another senna plant is *Cassia obovata;* and this also is sometimes called, by way of eminence, *Cassia senna*. It is a native of Upper Egypt, and was introduced to Britain before the middle of the 17th century. Its root is annual; its stem is about 20 inches high; and its flowers are yellow, and bloom in July and August. The leaves of this species are less purgative than those of *Cassia italica*, and constitute a considerable portion of the senna of commerce, but are generally mixed, even at the first native market, with those of *Cassia angustifolia* and those of *Cynanchum oleifolium*,—the former as good or nearly so as themselves, but the latter a downright adulteration.—A third senna plant is *Cassia lanceolata*. This is an evergreen undershrub of about a foot in height, and carries yellow flowers in July and August. It is a native of the Levant, and was long ago cultivated in Arabia, and is now cultivated on the coast of Malabar. The produce of it is somewhat extensively imported from Calcutta, and bears the name of East India senna.

Senna leaves emit a faint and somewhat disagreeable and sickening odour, and have a sweetish, slightly bitter, nauseous, aromatic taste. An infusion of them has a deep reddish brown colour, and possesses both their odour and their taste. Their active principle is a peculiar substance called cathartin. See the article CATHARTIN. Senna is a sure and comparatively mild purgative; but is liable to gripe, and requires to be accompanied with some aromatic. Decoction is a bad form of preparing it; but both the infusion and the powder are good; and in some cases, the tincture, the syrup, and the electuary are suitable.

SENSITIVE PLANT. Any one of several species of the genus mimosa,—though the name is most commonly given to the pink-flowered Brazilian biennial, *Mimosa sensitiva*. See the articles MIMOSA and IRRITABILITY. "The movement of the leaves of the *Mimosa pudica*," says Mr. C. Mackenzie, "have their origin in certain enlargements, situated at the articulation of the leaflets with the petiole, and of the petiole with the stem. Those only which are situated in the last articulation are of sufficient size to be submitted to experiment. If, by a longitudinal section, the lower half of this swelling be removed, the petiole will remain depressed, having lost the power of elevating itself. If the superior half be removed, the petiole will remain constantly elevated, having lost the power of depressing itself. These facts prove that the motions of the petiole depend on the alternate turgescence of the upper and lower half of the enlargement, situated at the point of articulation; and that contractibility is not the principle of these motions. If one part of the plant be irritated, the others will soon sympathise, or bear witness, by the successive falling of their leaves, that they have successively felt the irritation. Thus, if a leaflet be burnt slightly by a lens, the interior movement which is produced will be propagated successively to the other leaflets of the leaf, and thence to the other leaves on the same stalk. M. Dutrochet found that this interior movement is transmitted equally well, either ascending or descending; that it is equally well transmitted, even though a ring of bark has been removed; that it is transmissable, even though the bark and pith be removed, so that nothing remain to communicate between the two parts of the skin, except the woody fibres and vessels; that it is transmissable, even when the two parts communicate merely by a shred of bark; and that it may be transmitted, even when the communication exists by the pith only; but that it is not transmissable, when the communication exists merely by the cortical parenchyma. From these very interesting experiments, it results that the interior movement produced by irritation, is propagated by the ligneous fibres and the vessels. The propagation is more rapid in the petioles than in the body of the stem. In the former, it moves through a distance of from three to six tenths of an inch in a second; in the latter, through from eight to twelve hundredths of an inch, during the same portion of time. External temperature does not appear to exert any influence on the rapidity of the movement, but very sensibly affects its extent. Absence of light, during a certain time, completely destroys the irritability of the plant.

Such change takes place more rapidly when the temperature is elevated, than when it is low. The return of the sun's influence readily restores the plant to its irritable state. It appears, therefore, that it is by the action of light that the vital properties of vegetables are supported, as it is by the action of oxygen that those of animals are preserved; consequently, etiolation is to the former what asphyxia is to the latter."

SEPTAS. A genus of curious, evergreen, white-flowered, South-African, herbaceous plants, of the houseleek family. Three species, varying in the height of the flower-stem from 4 to 10 inches, have been introduced to the greenhouses of Britain; and they love a soil of sandy peat, and are propagated by division of the root. The name septas alludes to the curious fact that all parts of the flower are divided into seven.

SEPTEMBER. See CALENDAR.

SEPTFOIL,—botanically *Tormentilla*. A small genus of indigenous, perennial-rooted, herbaceous plants, of the rosaceous order.

The erect or officinal species, *T. erecta*, or *T. officinalis*, abounds in the heaths and coarse dry pastures of many parts of Britain. Its root is knotty and woody; its stems are erect, cylindrical, leafy, branched, diffuse or procumbent, and commonly about a foot high; its leaves are almost sessile, ternate, lanceolate, serrated, and hairy, and are accompanied with deeply incised stipules; its flowers stand on long, opposite, solitary, one-flowered footstalks, and have a golden yellow colour, and bloom from May till October; and its seeds are few and wrinkled. The root has powerfully astringent properties, and is a common and valuable remedy for intermittents and especially for diarrhœas and chronic purgings. It is used also, though not often, as a gargle or lotion for ulceration of the tongue and mouth, and as a local application to fetid and refractory sores. It is blackish without and reddish within, and has a slightly aromatic odour and an austere styptic taste, and yields all its active principles to boiling water. A dwarfish double-flowered variety of the plant, *T. e. flore-pleno*, occurs in some parts of Wales, but is rare.

The creeping or trailing septfoil, *T. reptans*, occurs about hedges and the borders of fields, and in some meadows and pastures, in various parts of Britain. Its stems are hairy and about two feet long, and have a prostrate but not creeping mode of growth; its stipules are undivided; its leaves stand on long hairy footstalks, and have each five leaflets, obovate, strongly serrated, and bright green; and its flowers are twice as large as those of the erect species, and have a full yellow colour, and bloom in June and July. This species also possesses astringent properties, but not in a sufficient degree to entitle it to a place in the Materia Medica.

SEPTUM. A partition in the interior or between the parts of any organism.

SERAPIAS. A small genus of curious, tuberous-rooted, brown-flowered, greenhouse, herbaceous plants of the orchis order. See the article ORCHIS.

SEROUS FLUIDS. Animal liquids of a whey-like appearance. Whey itself is the chief or normal serous fluid, or simply serum, and will be found noticed in our articles WHEY and MILK. The serum of blood is the thin liquid which separates during coagulation; and it has a yellowish colour, a slightly saline taste, a somewhat unctuous touch, and an average specific gravity of about 1·029, and possesses a slight alkalinity, and consists, according to Marcet, of 90 per cent. of water, 8·68 of albumen, 0·66 of muriate of potash and soda, 0·165 of carbonate of soda, 0·035 of sulphate of potash, 0·06 of earthy phosphates, and 0·4 of muco-extractive matter. The serous liquid secreted by the pleura, the pericardium, the peritoneum, and other serous membranes of the animal system, consists, according to Bostock, of 92 per cent. of water, 5·5 of albumen, 0·5 of muriate of soda, and 2 of mucus. The serous liquid which surrounds a fœtus, or what is often called the liquor of the amnios, differs in composition in different animals, and contains a peculiar acid in the cow.

SERRATED LEAF. A leaf whose edges are notched or indented in the manner of a saw.

SERRATULA. See SAW-WORT.

SERRURIA. A genus of ornamental, evergreen, Cape-of-Good-Hope shrubs, of the protea family. About 40 species have been introduced to the greenhouses and conservatories of Britain; and a number more are known. The introduced species vary in height from 1 foot to 8 feet; and most have purple flowers; and some require to be raised from seeds, though others are propagable from cuttings. The soil suitable for most is either a sandy or a peaty loam.

SERUM. See SEROUS FLUIDS.

SERVICE-TREE. Several species of rosaceous-flowered trees, of the pyrus or pear genus. They formerly were regarded as constituting a separate genus under the name of Sorbus.

The sweet or true service-tree, *Pyrus sorbus*—called by Linnæus *Sorbus domestica*—is a rare and somewhat doubtful indigen of moist woods in some parts of England, and probably was long ago introduced from the South of Europe. It presents a somewhat close resemblance to the mountain-ash, but is larger and more valuable. Its stem is upright, and commonly attains a height of about 30 feet; its young shoots have a downy or mealy appearance in summer, but incline toward a purplish colour, spotted all over with whitish spots, in winter; its buds, at the extremity of the shoots in winter, are turgid; its leaves are finely pinnated, and comprise seven or eight pairs of leaflets and a terminating odd one, and are broader and larger than those of the mountain-ash, and are more deeply and irregularly serrated, and have a much more downy under-surface; its flowers are white, and grow

in umbels, and bloom in May and June; and its fruit are large and fleshy, and have different shapes in the different varieties. This species takes the name of sweet or true service on account of the edibleness of its fruit; and it ranks as a dessert fruit-tree in France and Italy and some other parts of the Continent; but it has poor and scanty reputation as a fruit-tree in Britain. Its trees are slow in growth, and not early bearers; and require, for fruiting purposes, to be raised from layers,—and these make roots very tardily, and must remain at least two years in attachment to the parent-tree before they become fit for removal. Plants raised from seeds very rarely come true to the parental characters. The pear-shaped variety is the kind cultivated in orchards; and the fruit of it grows on the point of the branches, and requires, when gathered, to be laid in the fruit-room till the pulp passes into a state of decay; and it then has a comparatively mild acid taste, yet is seldom relished so much by Britons as the medlar.

The wild or griping service-tree, *Pyrus torminalis*—called by Linnæus *Cratægus torminalis*—grows wild in the woods and hedge-rows of several parts of England. Its stem commonly attains a height of about 50 feet; its growth is slow; its wood is hard; its leaves stand on long stalks, and are simple, seven-lobed, somewhat heart-shaped, serrated, and dark green; its flowers are white and numerous, and grow in large, terminal, downy, corymbose panicles, and bloom in April and May; and its fruit is umbilicated and not larger than that of the hawthorn, and becomes edible and agreeably acid when touched with frost or when partially decayed.

The mongrel or pinnatifid service-tree, *Pyrus pinnatifida*—called by Linnæus *Sorbus hybrida*—grows wild on rocky ground in some parts of England. It attains a height of about 40 feet, and is useful as a timber tree. Its stem is erect; its young branches are whitish; its leaves are very downy; and its flowers are white, and grow in umbels, and bloom in May and June.—Three other species of pyrus were comprised in the old sorbus genus, and may therefore be regarded as, in a sense, service-trees,—the common mountain-ash, the intermediate pyrus, and the small-fruited pyrus.

SESAMUM. See Oily Grain.

SESBANIA. A genus of ornamental, tropical, yellow-flowered plants, of the lotus division of the leguminous order. Two evergreen shrubs of about 4 feet in height, one biennial of about 6 feet in height, and 9 or 10 annuals of from 2 to 4 feet in height, have been introduced to the hothouse collections of Britain; and all bloom in July and August, and thrive in either common soil or a mixture of peat and loam, and are propagated from seeds. The oldest-known kinds were viewed by old gardeners as a sort of bastard sensitive plants.

SESELI. See Meadow-Saxifrage.

SESLERIA. A genus of grasses of the cynosurus tribe. The blue species, *S. cærulea*, grows wild in the moist, calcareous, rocky, upland fields and pastures of Britain. Its root is perennial, long, and strong, and forms dense tufts; its culms are smooth, simple, principally naked, and from 4 to 15 inches high; its leaves are linear, rather obtuse, keeled, and of a colour between sea-green and bluish; and its spikes are ovate, oblong, imbricated, about an inch long, and of a leaden colour sometimes inclining to purple, and have short, alternate, notched or jagged bracts, and bloom from April till June. This grass has an elegant and singular appearance, and is interesting to the botanist, but ranks only as a weed in the classification of the farmer. Seven or eight hardy, perennial species, varying in height from 3 to 20 inches, have been introduced to Britain from various parts of Continental Europe; but though some are ornamental, none possess any agricultural interest.

SESUVIUM. A genus of ornamental, tropical, herbaceous, red and white flowered plants, of the order Ficoideæ. Two annual species, and three perennial ones, varying in height from 1 foot to 3 feet, and all blooming in the latter part of summer, have been introduced to the hothouses of Britain from South America and the two Indias. The sessile-flowered species, *S. sessile* or *S. portulacastrum*, one of the perennials from the West Indies, 3 feet in height, and a herbaceous evergreen, contains a large quantity of saline matter, and is an excellent substitute for summer spinach.

SETARIA. A genus of grasses of the panicum tribe. Its species differ from the true panicums principally in having their panicles so contracted as to resemble spikes. Two species of economical interest and agricultural value are noticed in the article Millet. The green and the whorled species, *S. viridis* and *S. verticillata*, are annual indigens of respectively the sandy and the moist fields of some parts of England, and have a height of about 20 inches, and bloom in July and August. Upwards of 20 species, principally hardy annuals, have been introduced to Britain from various and widely-distant parts of the world; but all, as well as the true indigenous species, rank in the farmer's vocabulary as mere weeds.

SETON. A skein of thread or a piece of coarse tape looped through the skin of a horse or an ox, to act as a counter-irritant. It may be of any size or thickness, from very small to very bulky; and it admits of application to almost any part of the body. The tape is smeared or moistened with some digestive or stimulating unguent; and is passed beneath the skin by means of a strong flat needle; and ought to be secured at each end with a large knot of many ties or knots. Setons counteract inflammation in the same way as rowels, blisters, and cauteries; but they are the simplest and most manageable and most generally

applicable of counter-irritants, and can be used in situations and under circumstances where these other remedies are inadmissible. They are employed more commonly on the Continent than in Britain; but have of late years acquired increasing favour among British farriers. They serve particularly well in poll-evil, fistulous withers, and other ulcerative processes,—in chronic enlargement of the joints and ligaments and other parts,—and in all abscesses and diseases of the navicular region. In every case, a seton must be cleaned and moved daily, and dressed with common resin ointment; and in cases of their application to a sinuous track for the purpose of inflaming it, they must be renewed twice a-day, and moistened each time with oil of turpentine or tincture of aloes and benjamin or some similar stimulant.

SETTER. See Dog.

SEWERAGE. The drainage of towns. It comprises the rain water from the streets, the silty portions of mud from the yards and causeways, the foul water from kitchens, the refuse water of manufactories, the cleanings of water-closets, and, in general, all the filth and salts and organic matters which are not readily removeable in carts or waggons; and it is therefore very rich in at once variety, kind, and power of manurial ingredients. Even though it contained nothing more than nearly all the excrements, both liquid and solid, of the whole population, both brute and human, and though it held these in a state of very great dilution in otherwise useless water, it would be a highly valuable liquid manure; but it also contains other eminently fertilizing substances, and combines them and the excrements in proportions suited to the average wants of almost all field crops, and holds all in a state of comparatively great concentration,—and it is therefore well fitted to serve as a succedaneum for farm-yard manure, or rather, in fact, is in itself the very best of all general manures. The analysis of a specimen of it is given near the close of the article Manure; a good notion of its silty and least valuable portions may be obtained from the article Police Manure; a large instance of its tried power as a liquid manure for grass lands is mentioned in the article Irrigation; and striking ideas of the fertilizing energy of its most active and characteristic ingredients may be obtained from the articles Liquid Manure, Urine, Night Soil, Excrement, and Animal Manures.

A statement of the vast annual loss of manurial matters sustained by Britain, in several ways, but chiefly in the escape of sewerage to rivers and the sea, is made in the last section of our article Manure; and the following statement was made by a distinguished agricultural writer seven years ago, and has been abundantly borne out by more recent investigations respecting the condition of the metropolis:—"By carefully conducted experiments and very accurate gaugings, it has been found that the chief London sewers convey daily into the Thames about 115,000 tons of mixed drainage, consisting on an average computation, of 1 part of solid and 25 absolutely fluid matters; but if we only allow 1 part in 30 of this immense mass to be composed of solid substances, then we have the large quantity of more than 3,800 tons of solid manure daily poured into the river from London alone, consisting principally of excrements, soot, and the debris of the London streets, which is chiefly carbonate of lime; thus, allowing 20 tons of this manure as a dressing for an acre of ground, there is evidently a quantity of solid manure, annually poured into the river, equal to fertilizing more than 50,000 acres of the poorest cultivated land! The quantity of food thus lost to the country by this heedless waste of manure is enormous; for only allowing one crop of wheat to be raised on these 50,000 acres, that would be equal to the maintenance (calculating upon an average produce of 3 quarters of wheat per acre) of 150,000 persons. London, too, is only one huge instance of this thoughtless waste of the agricultural riches of the soil of England; from every other English city, every town, every hamlet, is hourly passing into the sea a proportionate waste of liquid manure; and I have only spoken of the solid or mechanically suspended matters of the average; the absolutely fluid portion is still rich in urine, ammoniacal salts, soda, &c., when all the mechanically suspended matters have been separated from the other portion. According to very careful experiments, this fluid part often contains 16 per cent. of animal matters, salts, &c., intimately or chemically combined with the water." The waste of sewerage, also, is a tremendous outspread of noxious exhalations and a dreadful polluting of useful streams, to the effect of marring the public comfort, injuring the public health, and constantly keeping up epidemics and pestilence; so that any measure which completely saves and economises sewerage for the purposes of manuring, at the same time acts as a mighty conservator of the life and well-being of both man and beast.

A great enterprise was recently commenced, by what is called the Metropolitan Sewerage Manure Company, for appropriating all the sewerage of London to manuring purposes; and this, it is to be hoped, will not only prove highly compensating to the parties interested in it, and eminently beneficial to the farmers and the market-gardeners who may avail themselves of it, but be speedily imitated in every city and considerable town of the empire. The whole plan is nearly a counterpart of that by which the city is supplied with water and with gas. Between the new house of Parliament and Stanley-bridge run two great sewers, the King's Scholars' Pond and the Ranelagh, both of them open, and some five or six small ones. The company makes an intercepting sewer from the first

of these to Stanley-bridge, of the capacity of 6 feet by 4¾. This sewer will run considerably deeper than either of the sewers it will intercept, and will be formed in the London clay, and completely covered in, so as to afford a perfect protection against the effluvia that proceed from the sewers as they now exist. Each sewer will be connected with the company's sewer by means of a shaft, with a shute, so that whenever they are not needed, the contents of the sewer may be sent through their former channel, and a grating at the mouth of the shaft will prevent the flowing in of solid substances. At Stanley-bridge this intersecting sewer will find its terminus, and there will the works of the company be stationed. The machinery is extremely simple. At the extremity of the sewer will be a tank, or well, from which the contents will be pumped, by means of a steam-engine of considerable power, into pipes precisely similar to those used by the water companies for conveying clean water. These mains will run along the high road, with branch mains into the side roads, and thence on either side, by means of service pipes, will the sewerage water be distributed to all who may desire to avail themselves of it; still observing precisely the plan by which the water companies carry the clean water through the streets of London. And much in the same manner as they supply the very summits of our houses with these mains, does the Metropolitan Sewerage Manure Company propose to supply the gardens and farms that lie on either side of their mains; with this difference in favour of the latter, that they have not to force the water up to the tops of high houses, but only along fields that are level, or almost so. And thus far, at least, there is nothing experimental or doubtful or difficult in the plan. The only novelty lies in the proposed manner of distributing the sewerage water to the soil, after it is conveyed to the immediate neighbourhood of the garden or farm by the mains running along the roads; and even this is done somewhat in the mode of the service pipes for the distributing of gas. Suppose a market gardener to desire a supply; a pipe will pass from the main into his garden; and there will be placed a stand-pipe, similar to those erected in all the streets in London for the use of the water-carts. If his gardens be large, he can erect at a very trifling cost as many stand-pipes as convenience and the saving of labour in conveyance of the sewerage may require. Thence he will be enabled to take an unlimited supply, at all seasons and at all hours, of the most fertilizing manure in the world! But upon farms, and where extensive grounds are to be manured, a singularly simple contrivance is to be adopted, by which the sewerage will be thrown over the land at the most trifling cost for labour, and with an uniformity and apportionment of quantity to the requisites of the soil, at present unknown, and indeed impracticable. The simple means for effecting this is the hose-pipe now in universal use for fire-engines. This pipe is perfectly flexible, so that it can be carried over hedges or walls, and laid in any direction, and yet offering so little resistance to the fluid, that in an experiment made at the New River Head, with a pressure considerably less than that proposed for the company's works, after passing through half-a-mile of hose-pipe, the jet from the mouth was thirty feet, and so powerful that it would have knocked a man down at a distance of five yards. But a hose-pipe of a quarter of a mile in length will suffice for the purposes of any farm, for that would permit the stand-pipes to be placed half-a-mile apart. Thus, then, when a farmer desires to manure his farm thoroughly, he has only to fix the hose-pipe to the stand-pipe: the former, being perfectly flexible, will run over hedges or gates—up hill and down dale; and in the field required to be manured, nothing more will be necessary than for one man to take in his hand the end of the pipe, from which will flow a jet from twenty to thirty feet, and play it upon the soil as easily as he would a watering-pot upon a flower-bed. And in this manner will one man be enabled to manure two acres and a half per day with more ease, and with tenfold more efficiency, than, with the present methods, five men could manure the same area in four days. The saving in labour alone will be enormous. And the price, too, will be a great consideration; for the present price of manure in the neighbourhood of London, laid upon the field, but not spread, is about ten shillings per ton, and the coast of spreading it adds about sixpence per ton; but the company will be enabled to supply the sewerage at the price of sixpence per ton; and as one man will be enabled to manure two acres in a day, the total coast of the manure and the spreading will be only from sevenpence to eightpence per ton. Another important advantage is, that the sewerage manure will afford a supply of water during summer, and serve for occasional irrigation during droughts. There can, therefore, be no doubt that it will be eagerly taken by the farmers, but still more so by the market gardeners, who now pay as much as from £15 to £20 per acre for manure.

SEYMERIA. A genus of ornamental exotic plants, of the figwort family. Two hardy annual species, the fine-leaved and the pectinated, both about a foot high, and carrying yellow flowers in July and August, have been introduced to Britain from North America.

SHACK. Waste corn left in the fields; also, live stock feeding on stubble land; also, land in an unenclosed state similar to that of a common. But the word, in all the senses, is provincial.

SHADDOCK,—botanically *Citrus Decumana*. A tropical evergreen fruit-tree, of the orange genus. It is a native of India, and was introduced thence to the orangeries of Britain in 1724; but it has long been naturalised and ex-

tensively cultivated in the West Indies, and is often regarded as a characteristic fruit-tree of that region. Its stem commonly rises to the height of about 15 feet; its leaves are ovate-lanceolate, thick, and shining; its flowers are white, and bloom from May till July; and its fruit is comparatively large, and possesses cooling and aperient properties, and has a taste somewhat similar to that of a fine orange, and, when of prime quality, is one of the most exquisite fruits in the world. But after the plant came to be generally grown in the West Indies, it greatly degenerated in consequence of bad culture, and of want of care to propagate fine varieties by budding. The fruit of good trees has red flesh and a luscious flavour; but that of most of the West Indian trees has pale yellow flesh and a harsh sour taste. The proper management of the shaddock-tree is similar to that of the orange-tree.

SHAKE. A disease in trees, consisting of long splits up the stem, and caused, in many instances, by violently bending the trees when young.

SHALE. See Soil, Marl, Clay, and Coal.

SHALLOT, Escalot, or Eschallot, — botanically *Allium Ascalonicum.* A hardy, perennial, bulbous-rooted, culinary plant, of the onion genus. It was introduced to Britain from Palestine about the middle of the 16th century. Its root is composed of a cluster of oblong bulbs; and is the part for which the plant is cultivated; and is used raw in salads, and cut small for sauce to boiled or fried meat. It has a stronger taste than the onion, yet is thought not to leave so strong an odour on the palate, and is therefore sometimes preferred to it. Each offset of the root, when properly planted and cultivated, becomes an independent luxuriant plant. The planting may be done either in October or November, or in February, March, or the beginning of April, at distances of 6 inches every way, in beds not more than 4 feet wide. In dry soil autumn planting is best; but in soil even moderately moist, spring planting is necessary, as the sets are very liable to be destroyed by moisture in winter. The time for taking up the bulbs is July or August. The flower-stem of the shallot-plant is about 10 inches high; and the flowers have a purple colour, and naturally bloom in June and July.

SHAMROCK. The national emblem of Ireland. It is commonly supposed to have been selected by St. Patrick as an emblematic illustration of the doctrine of the Trinity; it is inferred, from the taste and scholarship of St. Patrick, to be a plant of much elegance and beauty; it is known, from notices of it in old Irish writers, to possess a sour taste and to have been generally eaten by the ancient inhabitants of Ireland; and it has, for centuries, been most in request at the festival of St. Patrick in the month of March, and may therefore be supposed to have originally been in all its glory at that season of the year. What particular plant, then, is it? The word shamrock itself is merely a general Irish name for a trefoil, and gives no information. Common modern opinion points to the white clover,— *Trefolium repens;* but is widely at war with the conditions which we have stated. Mr. Bicheno, in a pithy and learned paper in the Journal of the Royal Institution, points, and we think points convincingly, to the common wood-sorrel,—*Oxalis acetosella,*—a plant which pushes forth its delicate leaves and blossoms with the earliest spring, and is more beautifully three-leaved than even the white clover, and must have formed a most agreeable and healthy salad to the old Irish, who lived chiefly upon flesh, and may be pronounced abundantly worthy of all the honours heaped upon it by both St. Patrick and the Irish people. The wood-sorrel, indeed, is now a comparatively scarce plant in Ireland, while the clover is plentiful; but, in the old times of the Irish forests, before arable cultivation became general, the wood-sorrel may have been plentiful and the clover scarce.

SHARE. See Plough.

SHAW. The haulm of potatoes, beans, and similar plants; also, a wood that encompasses a close. But the word, in both senses, is provincial.

SHEALING. A summer hut or temporary residence in a pastoral district. It used to be common in the Orkneys, the Hebrides, and some parts of the Scottish continental Highlands; and was often of very rude construction, and almost totally destitute of furniture. It was usually constructed in connexion with a system of summer-feeding of cattle, which was called "going to shealing," and which has been superseded by sheep-husbandry and agricultural improvement; and, by an easy metonymy, the name shealing was extended from the hut to the pasture and to the system. "After the crops had been sown, and the peats cut," says Dr. Robertson, in his Survey of Inverness, "the inhabitants removed annually, in the month of June, to their distant pastures, with all their cattle and families; and there, in some snug spot, the best sheltered in all the range allotted to the cattle, they resided for a certain number of weeks, until the pasture became scarce. A trusty person was sent before them to drive away any wandering cattle that might have trespassed within the bounds that were to be preserved. The men returned occasionally to the farm or home-stead, to collect the fuel, or hoe the potatoes, or weed the crop; and when the season for weeding the flax arrived, the women went home for that purpose. When the bounds are extensive, they have frequently more than one of these stations, which are called *ree* or *aree,* in the language of the country, and shealings in English. In such cases, the guardian of the grass was sent forward to another shealing, whenever the family arrived at that destined for their temporary residence. He was called

the poindler, probably because he had public authority to poind, (whence pound,) and confine the stray cattle, and to demand the fine established by law for the trespass. When these pastures were unusually rich, as at the head of a lake or by the sides of brooks in the valleys, the inhabitants of two or more farms associated together, and ate the grass of their shealings in common. This was the season of contentment, and often of festivity. The women employed themselves in spinning wool to clothe their families, and in making butter and cheese for part of their winter provisions; and the youths occupied themselves in fishing or athletic exercises; and at evening the primitive custom of dancing on the green and singing Gaelic songs was not forgotten. The shealings lasted from one to two months or more; and when the pasture was all consumed, they returned to their home steads."

SHEAF. A bundle of corn bound up on the harvest-field. See the articles Bands, Reaping, and Harvest.

SHEARING OF SHEEP. The yearly removal of the fleece of sheep with a pair of shears. The operation should be performed as soon as the old fleece is sufficiently raised from the skin by the growth of the young wool. The best time, in most cases, when the weather proves fine, is generally the early part of June; for when the operation is postponed till the latter part of that month, or especially till July, the carcase of any of the sheep who may be destined to the shambles before the close of summer is seriously injured, and the bodies of all the rest have not a sufficient defence against the mischievous and even destructive attacks of flies in the hottest time of the year. Eight days or so before the shearing, the sheep should be washed; and from that time till the day of shearing, they must be kept in a clean grass field where they cannot soil their wool under banks of earth. See the article Washing of Sheep.

The shearing may be done either under cover or in the open air; a large canvass sheet should be fastened upon the place, and, if necessary, made soft and cushion-like by spreading under it a layer of straw; and a sufficient number of sheep should be penned or housed in the immediate vicinity to keep the shearer or shearers constantly employed. "Everything being arranged, a shearer seizes hold of a sheep, and sets it on its rump at the tail head; and it is kept in that position by resting against his legs. He removes all straws, thorns, burs, or other things which may have adhered to the wool. In this position, the wool is removed from the head and neck, as far as the shoulders, the abdomen, scrotum, and edge of the thighs. The head of the animal is then bent down sideways, and its ribs on one side are curved round. This position is maintained by the shearer placing a leg on each side of the neck of the sheep, and pushing out the opposite ribs by pressing his knees gently against the ribs nearest to him. The wool is then shorn from the far side by the left hand of the shearer, by using the shears from the abdomen to the middle of the back, down as far as the loins. The animal is then placed in a similar position in an opposite direction, so that the right hand of the shearer is employed to shear the wool down to the loin, from the near side of the animal. The sheep is then laid flat on its side, and kept down by the shearer resting on his knee on the ground, and placing the leg between his knee, and the foot over its neck. In the position which the animal is kept down by the right leg, the right hand shears the wool from the near side of the hind quarter, and *vice versa*. The animal is then set at liberty. The wool shears in using should be held close to the body of the animal, with their points, which should be blunted, a little elevated. Every stroke of the shears should be short and narrow, to make a clean clip. The clips of the shears appear in concentric rings round the body of the sheep. The oil of the wool makes the shears clip smoothly; and they are sharpened with a whetstone." All cutting or wounding of the skin during the operation must be carefully avoided; for even the smallest will afford the flies an opportunity for lodging their ovules, and giving rise to maggots; and when any accidentally occurs, it should immediately be touched with a little tar, turpentine, resinous ointment, or sheep salve. A mark is commonly put on the newly shorn body, in order to facilitate the separation of the different classes of sheep on the farm. All dirty portions of the wool about the tail ought to be removed with the shears, and put together by themselves; and the separated fleece should be taken away by attendant women, and treated and laid past in the manner mentioned in the article Fleece. A shorn flock should be repeatedly examined soon after the shearing, with the view of detecting depositions of fly ovules; and all tumours indicative of these should be opened and rubbed with a little mercurial ointment. An ordinarily good workman will shear from 15 to 25 sheep a day; and a very expert one will shear more.

SHEARLING. A sheep that has been once shorn.

SHEARS. A large clipping instrument. Several kinds, of very different size and shape, and for widely different purposes, are used on farms. The sheep shears of the present day seem to be the same in form as the sheep shears used by the ancient Romans.

SHED. See Farm-Buildings.

SHEEP. A well known and important genus of ruminating animals. It comprises several wild species and a vast number of domesticated varieties or breeds. It is most extensively diffused, and exists and feeds and prospers under a vast diversity of conditions. The interest of it, in all its forms, to a zoologist, is very great; and

the importance of it, in its chief domesticated breeds, to farmers and entire nations, has always been high, and rapidly increases with the progress of civilization, of agricultural improvement, and of manufacturing enterprise. "No animal," says one writer, "varies more than the sheep, and none so speedily adapts itself to climate. It would almost appear that Nature had bestowed upon it a constitution so pliant as to enable it to accommodate itself to any point in a wide range of temperature; for it has accompanied man to every quarter of the globe, becoming impressed at every change with some peculiarity, alterable only by a change of situation, and varying, we might almost affirm, with the weather; for where the temperature is equable, there does the animal preserve an atmospheric stamp, and defy all efforts to alter the breed,—while, under a fluctuating sky, we can model it at will." "No other animal," says another writer, "is, in my opinion, worthy of so much attention as the sheep, it being alike valuable to the farmer and to the nation,—to the farmer, because it is raised with ease and in situations where other animals could not exist, and in general makes a better return for the quantity and quality of food consumed than any other animal,—to the nation, as supplying a staple article of food, and giving employment to thousands of artisans by the conversion of wool into manufactures. In fact, the production and general management of sheep claims to be treated as the foundation of good and profitable husbandry."

The general characteristics of the sheep as compared with those of the closely allied goat genus, are noticed in the article Goat; the principal wild species of sheep are described in the articles Argali and Musmon; the methods of improving and multiplying the domestic breeds of sheep are discussed in the articles Breeding and Crossing; some important points in the management of sheep, as to feeding and fattening, are treated in the articles Fold, Food of Animals, Feeding of Animals, Fattening of Animals, Aftergrass, Pasture, Grass Lands, Mustard, Turnip, Rye, and some others; the chief points in the management of ewes, with reference to reproduction, are discussed in the articles Abortion and Parturition; an important point, in the management of sheep flocks, when removing them from place to place, is noticed in the article Driving; the slaughtering of sheep and the preparing of their carcases for the market are treated in the article Meat; the characteristics and diversities of their flesh as food for man are noticed in the articles Mutton and Lamb; the properties, uses, and preparations of their other products are mentioned in the articles Wool, Milk, Cheese, Skin, Leather, and Horn; and the causes, symptoms, and treatment of diseases which attack them are discussed in the respective articles on these diseases, such as Braxy, Rot, Hydatid, Pining, Louping-Ill, Scab, Diarrhœa, Dysentery, Inflammation, Pneumonia, and many others. We therefore do not need, in the present article, to touch on any of these numerous topics.

General View of the Sheep Genus.—The generic characters of the sheep may be briefly stated as follows:—The horns are directed backward, downward, and forward, in a somewhat spiral form; the chaffron is naturally convex; a sinus occurs at the internal base of the toes in both the fore feet and the hind feet; two smaller toes or rudimentary hoofs occur behind the larger anterior pair; the tail is always short in the wild races, but varies in length in the domesticated breeds; the teeth amount in all to 32,—and comprise 8 incisors in the lower jaw, no incisors in the upper jaw, and 6 molars in each side of both jaws. But in its domesticated state, and very especially in its wild one, sheep are distinguished from goats and other species most nearly allied to them, far more by mental tempers and dispositions than by physical characteristics.

Wild races of sheep inhabit the elevated regions of Europe, Asia, Africa, and America, and comprise chiefly the several species and varieties of musmon and argali. They differ greatly from one another, and still more from the domesticated breeds, in habits and in specific characteristics; and, in some instances, they blend away into near resemblance to wild goats on the one hand or to domesticated sheep on the other; yet, in general, they exhibit very boldly the true characteristics of their genus, and may be regarded as, in many mixed methods, and often in their respective localities, the common or aggregate source of the multitudinous and very diversified domestic breeds. Some races of a medium character between wild and tame inhabit parts of Caubul, Persia, and the countries of the Turcomans and others in the regions round the Caspian Sea; and one of the best known of these has a very coarse grey hairy fur, outward-bent horns like those of the argali, and a head exactly similar to that of the ram on the ancient oriental sculptures; and this race, together with domesticated varieties of it, is the common cultivated sheep of a large portion of Arabia, Tartary, and Hindostan. Wild sheep, with seemingly other distinctive characteristics than those of any known existing races, are obscurely mentioned by ancient credible authors, or figure somewhat phantasmagorically in the descriptions of ancient fanciful writers. Whether any inhabited Western Europe, cannot certainly be affirmed; though the credulous chronicler Boetius speaks of sheep in the remote Hebridean island, St. Kilda, who had bodies larger than the largest goats, and horns longer than those of oxen, and tails reaching to the ground; and Pennant states that a bas-relief figure of an animal corresponding to this description was found on the wall of Antoninus in the vicinity of Glasgow.

The domestic breeds are prodigiously diversified, not only in modifications of the natural characteristics which they possess in common with the wild races, but in all the characters of shape and structure and wool and carcase and habit which belong peculiarly to themselves. Some of the rudest of them may easily enough be traced up to ancestral connexion with some one of the wild races; but the vast majority exhibit strong and intricate marks of a mixed descent; and some are, with good reason, supposed to show broad traces of a more or less free hybridizing with goats; and many or even most of the finer ones have resulted, either from a series of crossings between previously well modified breeds, or from the prolonged, steady, and combined influence of peculiar climate, peculiar food, and peculiar treatment. "We may believe, then," as Professor Low remarks, "that the domesticated sheep, the *Ovis aries* of naturalists, is a factitious species, and not one which has been called forth in the natural state. A species of this kind, however, having been formed, by whatever mixtures of blood, the members of it must have been subject, like every other family mixed or pure, to vary under the influence of external agencies; and thus, independently of the differences produced by differences of origin, there are those which have been produced by climate, food, and domestication, giving rise to those great varieties which, even under the narrowest geographical limits, present themselves." The longer, too, any species has been reduced to domestication, and the more complete its subservience to the human race, the greater and more remarkable will be the alterations which it undergoes. We need not wonder, therefore, that the very ancient dependence of the sheep on man as its lord and master, should have caused many signal variations from the character of the original type, or that repeated changes of food and climate, and the continuous action of an altered and artificial mode of management, should have produced a multitude of new or anomalous features. We accordingly find that, in most of our subdued varieties, the lengthened limbs and comparatively slender, though strong, active, and graceful forms of the original races have disappeared, and been replaced by heavy proportions, and a consequently indolent disposition,—and that the coarse, dry, brittle coating of hair has been succeeded by that woolly substance, of which human industry and ingenuity now form such abundant and manifold materials for the various uses of domestic economy, and the personal comforts of our race. The prodigious development of the wool, and almost entire disappearance of the hair, would indeed of themselves have sufficed to effect a complete alteration in the general aspect and physiognomy of the species; and this remarkable change has been produced in part by physical causes, and in part by the agency of man, who, aiding or counteracting as he best could the observed tendencies of nature, has contrived to subordinate a general law of climate to his own individual advantage.

The changes produced by domestication upon the dispositions and habits of the sheep are much greater than even those upon his physical properties, and render him eminently suitable to the uses of man, and adapted to the circumstances of enclosed pastures and artificial feeding. "When once completely subjugated, he never again appears to acquire the faculties which fit him for a life of liberty. Give him afterwards what freedom we may, he remains more or less dependent upon us, and would fall a prey to wolves and the swifter feræ, were he not under human protection. Yet he is not the stupid and insensible creature which some represent him to be. When entirely subdued indeed, his natural instincts are blunted, and he loses the providence and sense of danger which are natural to him; but when left in a state of comparative liberty, as on the mountains of Scotland and Wales, he shows that, though comparatively feeble, he is not without the power of guarding himself from danger. When attacked by dogs or foxes, the flock forms a circle, with the rams in front, presenting a face to the enemy. The rams rush forward on the assailant, and strike him with their powerful horns; and in their contests with one another for the possession of the females, they fight with amazing determination, stunning one another with the violence of the shocks. The sheep is an exceedingly hardy animal with respect to temperature, his close covering of wool defending him well from cold. He foresees an impending fall of snow, and takes shelter from its violence. When buried underneath the snow, as he sometimes is, he often survives for many days, and even weeks, and may be digged up without injury, provided he have escaped suffocation; for in such a situation, his thick fleece, which, as well as the snow, is a slow conductor of heat, retains the natural warmth of the body in such a degree as to preserve life. The ewe bears that affection to her offspring which Nature has imprinted, as it were, on the heart of every animal. Should mishap befal her young one, she mourns over it, and will not be comforted; should it wander from her side, her anxious bleatings are everywhere heard,—and the little creature rewards her cares with surprising fondness. Who that has seen shearing of the flock, has not marked the startled aspect of the lamb when the mother first runs toward it divested of her covering, and how quickly it is reassured, and how sensibly it expresses its joy, when it hears the well-known voice, and receives the wonted caresses! The sheep appears insensible and stupid, because it is rarely attached to us by acts of familiarity and kindness. But let the orphan lamb be brought up at the shepherd's cot, and fed from his hand, and we shall find it to be nearly as familiar as a dog,—

fond of being caressed, and unwilling to leave its protector to join its fellows of the flock. In countries where the shepherd guides his flock, and does not herd it by dogs in the manner practised in other places, the docility which the animals acquire is wonderfully great. Where the shepherd leads, they follow; they observe his motions and hear his voice,—and when he uses a pipe or horn, they listen to the well-known sound, and obey the signal. In the Alps of Switzerland, and in the mountainous parts of Italy, in Greece, and elsewhere, we are yet charmed with this remnant of pastoral simplicity and innocence. The shepherd boy knows all his little favourites,—he remembers their names, and, when called, they leave the flock and come to him. When the numbers are great, he selects a few, teaches them their simple lesson, and they become the guides of the rest to their allotted pastures, and learn to collect the wanderers. The music of the mountain shepherd we find to be no poetic fiction. In the mountains of the South, we yet hear the soft and artless tones of his pipe. In the morning he leads forth his little flock, and plays as he marches at their head, and at sunset returns in like manner to the fold, where he pens them, that they may be kept from the wolves."—[Low's Domesticated Animals.]

The connexions of sheep with their shepherd in the open, arid, sparce, precipitous hill-pastures of the East, where beasts of prey abound, and deep, dark, unscaleable chasms of vast depth and danger in the rocky mountains are numerous,—their profound dependence on him for protection from the most terrible forms of death,—their frequent need of restoration by him, at the peril of his own life, from dismal solitudes into which they have wandered,—their following him to the most verdant pieces of the hills and to the banks of purling brooks,—their knowledge of his voice, their attachment to his person, and the tender care and caressing affection which he continually renders them,—are beautiful and expressive emblems of the connexions of redeemed men with the Redeemer,—how they were all sought out by him in a waste and howling wilderness, and carried back on his shoulders to a place of safety,—how he laid down his life to save them, and took it again to tend them,—how he restores them to right paths, and leads them in green pastures and by still waters, and protects them with his mace and staff,—how they all know his voice, and follow him, and will not listen to a stranger,—and how, eventually and for ever, he will feed them and "lead them unto living fountains of waters" in the better land. "I, even I," said he, in reference to his ancient people, the mere types of his redeemed, "will both search my sheep and seek them out. As a shepherd seeketh out his flock in the day that he is among his sheep that are scattered, so will I seek out my sheep and will deliver them out of all places where they have been scattered in the cloudy and dark day, and will bring them to their own land, and feed them upon the mountains by the rivers, and in all the inhabited places of the country." Multitudes, in fact, of the most graphic passages of the Bible, descriptive of the Divine goodness to men, both for time and for eternity, abound in allusions to the habits and character and treatment of the sheep flocks of the East; and all, besides being exquisitely illustrative of some of the most momentous truths of revelation, place these truths in a light of intense interest and wondrous beauty, to persons who have carefully observed even the mountain flocks of the sheep of our own land.

Sheep were domesticated so early as the lifetime of the first man; and they make a somewhat conspicuous figure in the earliest records of the oldest nations. "Abel was a keeper of sheep;" and all the chief patriarchs, whose characters are sketched in the inspired record, were possessors and tenders of flocks. The sacred scriptures make historical mention of sheep from the earliest times, through all the patriarchal ages, down to the epoch of the kings; and they often describe flocks of them with a richness of colouring and a minuteness of detail which identify the pastoral usages of remote periods with the practices of the wandering shepherds of the East at the present day. "Scarcely anything seems to have changed in the habits of men in those countries of pastoral tribes. Where Abraham pitched his tent, with his sheep and oxen and asses and camels,—where he sat at the door of his tent,—where the stone was rolled from the wells from which his maidens drew water,—there the Arab or the wandering Turcoman encamps, and all the scene is like a vivid panorama of the past. In the case of the present people of the Desert,—their tents, their journeyings, their household cares, their flocks, their camels, their wells,—all inform us with what a matchless fidelity the Sacred History has been told." The sheep figures also in the earliest records of the nations of Southern Asia, on the oldest existing monuments of Western Asia, on the sculptured remains of ancient Egypt, and in the symbols and memoranda of the earliest arts and sciences of the whole civilized world. It was probably introduced to Southern and Eastern Europe, in some of its best or most improved Asiatic varieties, at the very dawn of European civilization; it was highly esteemed by the ancient Greeks, and is prominently and honourably mentioned by their historians and poets; it was introduced to Italy after the foundation of Rome; it probably was introduced to Spain at an early period from Africa; and it seems to have become diffused throughout all western and central and north-eastern Europe at the period of the Roman conquests. In recent times, it has commanded rapidly increasing attention; and at the present day, in the most highly improved agricultural countries of the world, it is more multitudinous,

and possesses a wider connexion with the interests of husbandry, than at any former period.

The names given to the domestic sheep in Britain vary according to sex, age, and other circumstances. "The male," says Mr. Youatt, "is called a ram or tup. While with his mother, he is denominated a tup or ram lamb, a heeder, and, in some parts of the west of England, a pur lamb. From the time of weaning until he is shorn, he has a variety of names; being called a hog, a hogget, a hoggerel, a lamb hog, a tup hog, or a teg, and if castrated, a wether hog. After shearing, when probably he is a year and a half old, he is called a shearing, a shearling, a shear hog, a diamond or dinmont ram or tup, and a shearling wether when castrated. After the second shearing, he is a two-shear ram or tup or wether; at the expiration of another year, he is a three-shear ram, &c.; the name always taking its date from the time of shearing. In many parts of the north of England and Scotland he is a tup lamb, after he is salved and until he is shorn, and then a tup hog, and after that a tup, or if castrated a dinmont or a wedder. The female is a ewe or gimmer lamb until weaned, and then a gimmer hog, or ewe hog, or teg, or sheeder ewe. After being shorn, she is a shearing ewe or gimmer, sometimes a theave or double-toothed ewe, or teg; and afterwards, a two-shear or three-shear, or a four or six-tooth ewe or theave. In some of the northern districts, ewes that are barren, or that have weaned their lambs, are called eild or yeld ewes."

The Varieties and Breeds of Domesticated Sheep.—The domesticated sheep of different countries present an almost endless diversity of form, size, fleece, and other characters; and might, in consequence, be arranged into many groups, and distributed into almost innumerable varieties. Those of Asia comprise two grand classes,—the one with flat tails naked underneath, the other with long, round, wool-clothed tails,—both comprising a great many kinds with widely different characters,—and the former including some remarkable varieties with enormous masses of fat either on the tail or on the haunches. Those of some parts of Africa, as in the north-east, are similar to some of the Asiatic races; those of other parts, as in the north-west and in Abyssinia and Congo, are peculiar, and comprise some very large long-legged kinds; and those of other parts, as in the vast regions of the interior, are in a great measure unknown, but are supposed to be more or less peculiar, and to comprise many varieties. Those of Europe are amazingly diversified, and exhibit very marked indications of a mixed descent, and are generally supposed to have wholly or at least chiefly sprung from crosses and climatic modifications of the imported breeds of Asia and Africa. Even those of the British Islands present extraordinary diversities of size, form, wool, habit, and other characters, and have obviously descended from widely different and manifoldly commixed sources, and seem to exhibit, in no small degree, the effects of the prolonged influence of climate, food, and peculiar treatment, as well as the results of systematic crossing and highly artificial management. We shall, in the sequel of this section, give a brief account, first of some of the most remarkable foreign breeds, and next of all the principal or well-defined British breeds.

The long-legged African sheep, which natively belongs to the coast of Guinea and to some other districts, is probably the largest and tallest of all the domestic varieties. It is $4\frac{1}{2}$ feet long and upwards of 3 feet high; and it resembles the wild musmon in outline of countenance and in general deficiency of wool. The chaffron is arched; the ears are frequently pendant; the neck is short; the legs are remarkably long; the tail reaches to the heels; the skin of the throat is frequently pendant; and the horns are generally short, and form not quite an entire circle round the ears. The colour varies from white to brown, black, and pied; and the covering comprises portions of wool on the croup, back, and flanks, but consists elsewhere of hair, which, on the nape of the neck and shoulders, assumes the form of a heavy mane hanging down to the breast. This animal was introduced to Europe by the Dutch, and naturalized in East Friesland. A cross of it with the common breed produced the Texel sheep or *Mouton Flandrin*, the ewe of which is remarkable for always producing several lambs every year, and whose wool, while possessing a certain degree of fineness, is of great length.

The Morocco sheep has a somewhat near affinity to the long-legged Guinea sheep, yet possesses some decided characteristics of its own. The wool of it is long; the hair on the neck is short, undulating, and of a rufous brown colour; the ears are small and horizontal; the horns are small and turn spirally outwards; the scrotum forms two separate sacs; and the general colour is white, with markings of liver-coloured brown. A specimen of this breed was at one time in the possession of the late Sir Joseph Banks.

The Congo sheep is also akin to the long-legged Guinea sheep. Its proportions are similar; but its flanks are hollower, its chaffron is greatly arched, and some of its other characters are widely different. It is meagre and powerless; and, instead of wool, is covered with loose hair, slightly lengthened beneath the throat. The horns are short, and turned back upon the neck; the ears are pendulous; the throat is wattled or pouched; and the tail is very long, slender, and almost naked. The general colours of the fur are composed of large clouds of rufous coloured brown upon a white ground. The females are hornless.

The Angola breed are better proportioned. The chaffron is scarcely arched; the horns are small; and the wool, at least on those called Coquos, is finer and more abundant. The others

are rather hairy. In all, the tail is very long, the ears only horizontal, and the prevailing colour white, with broad rufous spots. Of the Angola race, one of the most remarkable is the Zunu or goitred breed, which is low on its legs, the hairs close, the ears pendulous, and the tail reaching to the fetlocks. It is very delicate, and has a singular mass of fat, in the form of a high collar, behind the horns, and resting on the occiput. The horns are short, slender, and turned inwards towards the forehead. Upon the larynx another mass of fat hangs like a goitre, under the throat; and the forehead is so prominent, that a deep depression occurs between the eyes. The ears, neck, body, and superior part of the tail are pale brown; the head, goitre, throat, legs, belly, and inferior half of the tail, white.

Broad-tailed sheep form a class or great group, and comprise several varieties which inhabit far-distant countries, and which, while they agree in the character of the tail, differ from one another in some other particulars. They are generally of a medium size, the chaffron arched, the ears pendant but mobile, and the wool coarse and long, and hanging in thick patches. The horns are large and directed first backwards, and then downwards and forwards; and they are sometimes quadruple, and sometimes entirely wanting. The tail is greatly enlarged laterally, in consequence of an enormous accumulation of fat in the cellular tissue; it is naked and flesh-coloured beneath; and its interior surface is marked by a slight longitudinal furrow.

The Hottentot broad-tailed sheep is characteristic of Southern Africa, although it now occurs also in Madras and Bengal. It is of small size, and handsomely made. The tail, the end of which is turned up and sharp pointed, is furnished beneath with a considerable expanse of fat, which is rather thick than laterally spread; the wool is replaced by short soft white hair; and the tips of the ears, the knees, houghs, fetlocks, and a spot around each eye, are fulvous. This is a delicate variety, almost entirely useless as sea-stock, as it usually perishes during the first gale of wind. It is one of a vast race, which, according to Major Smith, is spread, with various modifications, over Egypt, Barbary, the Levant, India, China, and Russia.

The North African broad-tailed sheep is not uncommon in Barbary, and is sometimes found even in the island of Corsica. It has three or four horns, and pendulous ears; and its tail is not very broad. Its general colour is white, the posterior parts being covered with wool, and the head and shoulders with loose soft hair. A breed of this kind crossed with the Emmemas or Guinea sheep, was in the possession of Mr Wilding. Its entire covering consisted of soft silky hair, of a silvery whiteness. The hair of the fore and hind part of the neck was of great length; and there was a black spot on each knee and thigh. So forcibly was this animal acted upon by the colder climate of England, that in the month of November it began to assume the soft woolly coat of our native breeds.

The Astracan breed is remarkable in its youth, for the beauty of its fine frizzled coat, frequently used in the natural state as furs. These are taken from the lambs, of which the mothers are slain a few days previous to yeaning. The adults are covered with longer and coarser wool, beneath which the black and white coating of the young may be detected, but not in the frizzled state.

In northern and middle Asia, another broad-tailed breed occurs, remarkable for having four, five, and even six horns. The ears point forwards and downwards, the throat is wattled, the chaffron convex, and the wool coarse. This breed is found along the banks of the Wolga and Jennissai, and forms the flocks of the Kirguise.

The fat-rumped sheep of Southern Russia is, in a sense, a broad-tailed breed, yet perhaps belongs to another and peculiar race. The caudal vertebræ are very few; and on each side of the tail there is a large rounded mass of fat, separated beneath, but united at the tail itself. This breed is characteristic of the Steppes of the south of Russia, but also occurs in Persia and China. The wool is coarse, frequently dark coloured, or nearly black; the hoofs are long; and the ears are pendulous.

The fat-rumped sheep of Tartary has long pendulous ears, and a very short tail. The quality of the wool is good, but the colour is mixed,—that of the male being roan, or light brown, mingled with white, and that of the female black and white. This is probably the species figured by Bewick, although he states, that, instead of a tail, it had merely a large protuberance of fat behind, covering the rump. It appears to have either no horns at all, or very small ones.

A variety of the fat-rumped sheep of Tartary, seemingly crossed with the sheep of Astracan, is found in the Mysore. It is hornless, with narrow pendulous ears and a very short clean tail; and the wool, very fine, is particularly curled, in small meshes, shaped like a cork-screw; the eyes are blue, and the colour pure white. It is the most beautiful breed of India. The late Sir Joseph Banks had a specimen which came from the Gardens of Tippoo Sultan, at Seringapatam.

The long-tailed sheep, like the broad-tailed ones, form a class or group; but they are, as yet, obscurely known. The tail is so long as to trail upon the ground; the horns are middle-sized, and twist spirally from the side of the head; and the wool is coarse, and frequently black. Some breeds of this group are found in Circassia and the south of Russia.

The many-horned sheep of Iceland is one of the most remarkable of the European breeds. It is a small animal; and has large irregular horns, varying in number from two to six, or even more, and not turned spirally, but simply

Musk Ox Vol. III. Page 177

Waldeck & Stuart

curved backwards, upwards, or to one side. The coat shows a beautiful adaptation to the rigours of the Icelandic climate, and consists as it were of three layers,—long coarse hair, thick intermediate wool, and fine close interior down. The head, tail, and extremity of the limbs, are covered with short hard hair. The hoofs are long, narrow, and irregular, in consequence of the animals living so much among the soft snow, which scarcely wears them. Another breed, large and white, likewise occurs in Iceland, distinguished by the same peculiarities in the form and number of the horns. This has probably been obtained by a cross from some continental race. The Icelanders feed their sheep, when the summer crop happens to fail, on fish bones. They also observe that their flocks fatten rapidly when they can obtain a good supply of scurvy-grass.

The Wallachian sheep are also a strongly characterised European breed, and have been regarded by some authors as a distinct species. The horns of the male are remarkable for their length and upright position, and form a complete spiral turn at their base, and then ascend spirally upwards; and those of the female are divergent, and twisted on their own axes. The fleece is long, coarse, and undulating; the ears are small and drooping; and the tail is long. The general colour is white; and the dimensions equal those of an ordinary sized sheep. This is a handsome showy animal, common in Hungary and Wallachia, from which numerous flocks are driven to the market of Vienna. Belonius says they occur in Crete; and the ancients are supposed to have described them under the name of *Strepsiceros*.

The Merino or Spanish sheep is the most celebrated of all the European breeds. This variety is distinguished by the size and strength of its horns, which form a regular spiral turn on the sides of the head, and by its wool, twisted in cork-screw ringlets, and beautifully soft and fine. The breed, though said originally to have come from Barbary, is now widely spread, and in great perfection, over Spain; and many of the most esteemed of the French races owe their excellence to a preponderance of the Merino blood. There seem to be two principal kinds of sheep in Spain,—the coarse-woolled, which always remain in their native pastures, and are housed every night in winter,—and the fine-woolled, which are always in the open air, and travel every summer from the cool mountains of the northern parts of Spain, to feed in winter on the southern and warmer plains of Andalusia, Mancha, and Estremadura. M. Bourgoanne, a French gentleman, who resided many years in Spain, gives the following account of the wandering sheep of Segovia: "It is in the neighbouring mountains that a part of the wandering sheep feed during the fine season. They leave them in the month of October, pass over those which separate the two Castiles, cross New Castile, and disperse themselves in the plains of Estremadura and Andalusia. For some years past, those of the two Castiles, which are within reach of the Sierra Morena, go thither to pass the winter, which, in that part of Spain, is more mild. The length of their day's journey is in proportion to the pasture they meet with. They travel in flocks from 1,000 to 1,200 in number, under the conduct of two shepherds, one of whom is called the Mayoral, the other the Zagal. When arrrived at the place of their destination, they are distributed in the pastures previously assigned them. They return in the month of April; and, whether it be habit or natural instinct that draws them towards the climate which at this season becomes most proper for them, the inquietude which they manifest might, in case of need, serve as an almanac to their conductors. The Leonese races (among which that called *Cavagne* is the most distinguished), after having been cantoned during the winter near Merida in Estremadura, on the left bank of the Guadiana, are marched about the 15th of April, in flocks of 2,000 and 3,000, across the Tagus at Almarez to Villa Castin, Trescasas, Alfaro, Espinar, and other stations, where their fleeces are shorn; and when this operation is completed, each division continues its route towards the province of Leon, where it is partitioned into flocks of 500 over the pasturages of Cervera, in the neighbourhood of Aquilar del Campo. The Soriane races, dwell during winter in the confines of Estremadura, Andalusia, and New Castile. Towards the end of April, they cross the Tagus, at Talaveyra de la Reyna, and the Puente del Arzobispo, when their march is directed towards Madrid, from whence they travel to Soria, where a portion is placed among the neighbouring mountains, and a portion crosses the Ebro, and is located on the pastures of Navarre and the Pyrenees. All these wandering races are known under the general denomination of Transhumante. The most esteemed among the stationary tribes, or Estantes, dwell behind the gorges of the Guadarama and of Somosierra, and in the environs of Segovia, near certain residences, called Esquileos, where the sheep-shearing is carried on." The Leonese excel all the other breeds, both in the form of their body and in the abundance and quality of the wool.

The form of the Merino sheep does not accord with the English ideas of symmetrical proportion; and the pendulousness of its skin beneath the throat is particularly offensive to the eye of an English breeder; but the fleece, besides being remarkable for its bulk and character, affords three distinct kinds of wool,—one from the back and belly, another from the neck and sides, and a third and coarsest from the breast, shoulder, and thighs. "The first impression made by the Merino sheep on one unacquainted with its value," says Mr. Youatt, "would be unfavourable. The wool, lying closer and thicker over the body than

in most other breeds of sheep, and being abundant in yolk, is covered with a dirty crust, often full of cracks. The legs are long, yet small in the bone; the breast and the back are narrow, and the sides somewhat flat; the foreshoulders and bosoms are heavy, and too much of their weight is carried on the coarser parts. The horns of the male are comparatively large, curved, and with more or less of a spiral form. The head is large, but the forehead rather low. A few of the females are horned, but, generally speaking, they are without horns. Both male and female have a peculiar coarse and unsightly growth of hair on the forehead and cheeks, which the careful flock-master cuts away before shearing time; the other part of the face has a pleasing and characteristic velvet appearance. Under the throat there is a singular looseness of skin which gives them a remarkable appearance of throatiness or hollowness in the pile; the pile when pressed upon is hard and unyielding; it is so from the thickness with which it grows upon the pelt, and the abundance of the yolk detaining all the dirt and gravel which fall upon it; but when examined, the fibre exceeds in fineness, and in the number of serrations and curves, that which any other sheep in the world produces. The average weight of the fleece in Spain is 8 pounds from the ram and 5 from the ewe; when fatted, these sheep weigh from 12 to 16 pounds per quarter." But, on the other hand, the Merinos have very serious defects. "When we regard them as animals to be fattened for human food," says Professor Low, "they are of an inferior class. Their flesh is of indifferent quality, and they are of tender constitutions. The females are the worst nurses of any race of sheep which inhabit Europe. So great is their defect in this respect, that in Spain half the lambs are killed in order that the ewes may be enabled to suckle the remainder, it being calculated by the Spanish shepherds that the milk of two ewes is required to bring up one lamb in a proper manner. Abortions are frequent, parturition is difficult, and the ewes are more apt to desert their offspring than any other sheep which are known to us. In these respects, the Merinos resemble the ancient *Oves molles* of Italy, which were remarkable for the delicacy of their constitution, their voracity, unthriftiness, and inferior power of secreting milk. The Spanish Merinos, although retaining a certain degree of wildness, are yet very docile in their tempers. No sheep place themselves more unreservedly under the guidance of the shepherds; and, although late in arriving at maturity, and difficult to be fattened, they are readily satisfied with dry and innutritious pastures. When put amongst other sheep, they keep together, generally on the higher grounds. At night they form themselves into a circle, the rams and stronger sheep being on the outside, retaining thus the instincts which they had acquired in their native habitation." The Merino breed were introduced to Britain in 1788, and pushed into prominent notice among British farmers in 1804, and taken under the special protection of a great and influential public society, instituted for the purpose, in 1811; and they have, in a great diversity of places and circumstances, both by themselves and by intermixture with other breeds, been put to a very ample trial in our country. All the crosses from them, however, have either so totally failed or been so excessively diluted, that they may already be regarded as quite extinct; and though the pure naturalized Merinos have entirely succeeded, and are found to improve in size, in lactiferousness, in length of wool, and in external form, yet they are not hardy enough for all ordinary situations, and do not yield so much profit to the farmer as some of the best British breeds.

The French sheep, commonly called Mouton de Picardie, de Brie, de Beauce, are of medium dimensions, and measure about 2 feet 4 inches (French) in height at the shoulder. The rams are usually hornless, the head narrow, and, in common with a portion of the neck and legs, covered with a short, rough, hairy coating. The wool of the body is coarse and abundant, and hangs in large separate masses, composed of straight untwisted filaments. The usual colour is white. The French writers distinguish several varieties, or mixed races, which, like our own, commonly bear the name of the district of which they are the most characteristic. La Flandrine is long and tall, and is supposed to have originated from a cross by an African ram; it is also called mouton de Texel. La Solognote has a fine slender head, usually hornless, and the wool frizzled at the extremity of the meshes only. La Berichonne is distinguished by the length of its neck. The head is without horns, and furnished with wool on its summit. The fleece is fine, white, short, close, and frizzled. La Roussillonaise produces a very fine wool, which partakes of the nature of the Spanish fleeces, being spirally twisted in a similar manner. It has probably been crossed with the Merino race. There are many demi-merinos in France; and of these the wool is usually longer, though less fine, than that of the true Spanish breeds.

The British breeds of sheep have been classed into horned and hornless, into long-woolled and short-woolled, into upland and lowland, into ancient and modern, and into natural and cross. But they may, much more fully and with far greater advantage, be distributed into the Scottish Insular, the Welsh, the Irish, the English forest, the old upland, the mountain, the down, and the long-woolled. According to this classification, the Scottish Insular breeds comprise the Shetland and the Hebridean; the Welsh breeds comprise the mountain Welsh, the soft-woolled Welsh, and the Radnor; the Irish breeds comprise the Wicklow, the Kerry, and the long-

woolled Irish; the English forest breeds comprise the Dartmoor and the Exmoor; the old upland breeds comprise the old Norfolk, the Penistone, the old Wiltshire, the Dorset, the Somerset, the Portland, and the Ryeland; the mountain breeds comprise the blackfaced heath, the Herdwick, and the Cheviot; the down breeds comprise the Southdown and the Hampshire down; and the long-woolled breeds comprise the Lincoln, the Romney Marsh, the Bampton-Nott, the Cotswold, the new Oxford, and the Leicester.

The Shetland sheep are small handsome animals, with short fine fleeces. They comprise numerous subvarieties, and have been somewhat largely crossed, in many places, with breeds from the nearest parts of Continental Europe; yet they possess a quite marked family character, and may all, more or less, be readily ascribed to a common origin. They are wild, active, and very hardy; and have slender limbs and short broad tails; and either are hornless or have short and often straight and upright horns similar to those of the goat. Some are white, some black, some brown, many grey, and many curiously streaked or otherwise marked with intermixtures of black and white. Their wool is soft and cottony, and adapted to very fine manufactures, and has, in some instances, been found to rival the merino wool. "They have three different successions of wool yearly, two of which resemble long hair, more than wool, and are termed by the common people *fors* and *scudda*. When the wool begins to loosen in the roots, which generally happens about the month of February, the hairs or *scudda* spring up; and when the wool is carefully plucked off, the tough hairs continue fast, until the new wool grows up about a quarter of an inch in length, then they gradually wear off; and when the new fleece has acquired about two months' growth, the rough hairs, termed *fors*, spring up, and keep root, until the proper season for pulling it arrives, when it is plucked off along with the wool, and separated from it at dressing the fleece, by an operation called forcing. The *scudda* remains upon the skin of the animal, as if it were a thick coat, a fence against the inclemency of the seasons, which provident Nature has furnished for supplying the want of the fleece. The silver-grey wool is thought to be the finest; but the black, the white, the *mourat* or brown, is very little inferior; though the pure white is certainly the most valuable for all the finer purposes in which combing wool can be used." The Orkney sheep are radically the same as the Shetland sheep, but have been more frequently mixed with other breeds, particularly with the Dutch, and have not so fine wool.

The Hebridean sheep possesses considerable affinity to the Shetland sheep, but is among the smallest of its kind, and of comparatively little value. Its shape is thin and lank; its horns are usually short and straight; its tail is very short; its face and legs are white; and its wool is sometimes bluish-grey, sometimes brown, sometimes deep russet, and sometimes a combination of all these colours. The carcase, on the average, does not weigh more than about 20 or 22 lbs.; and the wool is proportionally small in quantity, and has different qualities on different parts of the same fleece, but, under favourable circumstances of pasture and management, is very fine and has a softness similar to that of the Shetland sheep.—A remnant of an ancient race of sheep occurs in several of the northern counties of Scotland, characterised by yellowness of face and legs, and by dishevelledness and unequal quality of fleece, part of it being fine and part coarse.

The Welsh mountain sheep are similar in size to the Hebridean sheep, and have horns and habits similar to those of goats. They are wild and very active, and frequent the highest parts of the mountains, and feed largely on alpine aromatic herbage. They have black hair on their face and legs, and a ridge of hair on the back, throat, and dewlap; and their fleece is of various colours,—principally black, brown, and grey.—The Welsh soft-woolled sheep are also a mountain breed, and only about one-sixth or one-fifth larger than the preceding breed; but they are much more valuable, and far more generally diffused, and may be regarded as the distinctive breed of Wales. They have exceedingly active habits, and cannot be confined within any low or ordinary enclosures. Their general form is slender; their hind-quarters are long, and somewhat similar to those of the deer; their neck is thin, and is more arched backward than that of any other variety of sheep; their coat contains some mixture of hair, though less than that of other mountain breeds; their throat is so hairy as to have a sort of beard; their fleece weighs between one and two pounds, and is long-woolled, and furnishes the material for the well-known Welsh flannel; and their flesh is of excellent quality, and has long been celebrated under the name of Welsh mutton. A subvariety of this breed, of a larger size and better fed, occurs in Anglesea.—The old Radnor sheep possesses some resemblance to the Welsh soft-woolled sheep, and a greater one to the Welsh mountain sheep, but has a larger size and a better shape than either, and is probably a mixed offspring of the two enlarged and improved by feeding on better pastures.—The new Radnor sheep is an improved subvariety of the old, and has been crossed with the Shropshire and other breeds, and is often the only sheep meant when farmers of the present day speak of the Radnor.

The Wicklow sheep inhabit principally the Wicklow mountains on the east coast of Ireland; and they considerably resemble the mountain and the soft-woolled sheep of Wales, in both form and habit. They are small and wild; and comprise a comparatively small-sized and coarse-

woolled variety in the poorest and loftiest situations, and a comparatively large-sized and fine-woolled subvariety in the richer and lower situations. They have no horns; their faces and legs are generally white, but sometimes black; their wool is tolerably fine and rather long; their neck and back, especially in the loftiest and bleakest pastures, are protected by a ridge of hair which causes the rain to shoot off; and their flesh is excellent, and causes the lambs to be in great request for the Dublin shambles.

The Kerry sheep are the most characteristic of a number of small mountain breeds who inhabit the highland districts of the west coast of Ireland. They are larger than the Wicklow and the Welsh mountain sheep; yet they feed and grow slowly, and are comparatively unthrifty. They present some general resemblance to the antelope races; and are hardy, active, restless, and roaming. Their shape is never full or rotund; their fat accumulates only in the interior; their wool is coarse and hairy on the back and haunches, and fine and soft on the ribs; and their flesh, in general, is excellent.

The long-woolled sheep of Ireland comprise many subvarieties; and are diffused throughout all the Irish plains and valleys. The aboriginal breeds of them, and even those which at no remote period furnished the main supply to the great annual fair of Ballinasloe, were large in size, exceedingly coarse in form, and very unthrifty in feeding and fattening habits. "I never," said Mr. Culley, "saw such ill-formed ugly sheep as these. The worst breeds we have in Great Britain are much superior. I know nothing to recommend them except their size, which might please some old fashioned breeders, who can get no kind of stock large enough. They are supported by long, thick, crooked, and grey legs; their heads long and ugly, with large flagging ears, grey faces, and eyes sunk, necks long, and set on below the shoulders; breasts narrow and short, hollow before and behind the shoulders; flat-sided, with high, narrow, herring backs; hind quarters drooping, and tail set low." But these ungainly creatures, ever since about the time when Mr. Culley wrote, have been more or less crossed with other breeds, principally the new Leicester; so that their successors of the present day, though still faulty and inferior, have lost all the old excessive ugliness, as well as a good measure of the other bad points. The long-woolled Irish sheep now do well for the butcher, but ill for the wool-merchant, and indifferently for the breeder. Their heads are large; their sides are flat; their breasts are narrow; their general form is coarse; and their fleece is harsh and of medium quality and weight.

The Dartmoor sheep are hardy, and well adapted to the district from which they take their name. They are small, wild, restless, and difficult to be confined; but though bred on the heath, are commonly fattened on the plains. They grow slowly, and attain an average weight of about 10 lb. per quarter. Their face and legs are white; their wool is soft; and their flesh is in much demand, not only in near but in distant markets.—The Exmoor sheep are rather smaller than the Dartmoor, but greatly resemble them in general appearance, in disposition, in habits, and in value. Their head, neck, and bones are small and delicately formed; their body is comparatively narrow and flat-sided; and the males have a beard under the chin somewhat like that of goats.

The Norfolk sheep are a wild hardy race, and were formerly diffused through the sheep-walks of Norfolk, Suffolk, and Cambridgeshire. They are voracious eaters, and have a restless disposition, and cannot easily be retained in limited pastures. They have large spiral horns, black faces, and long, large-boned, dark-grey legs. The carcase is small, lengthened, thin, and weak, with a narrow chine, and weighs from 16 lb. to 20 lb. per quarter. The flesh does not stiffen well in hot weather, and is supposed to become tainted sooner than most others. The wool is short and fine, and seldom weighs more than 2 lb. In many places, this breed have been crossed with the down sheep, and very greatly improved; and in others, where they were at one time reckoned good folding sheep, they have been entirely and profitably superseded by the Southdowns.

The Penistone sheep inhabit a heathy district of about 500 square miles in extent on the mutual borders of Yorkshire, Derbyshire, and Lancashire. Their general form, and especially their extremities, are very coarse; their face and legs are white; their shoulders are heavy; their limbs are bony; their feet are large; their sides are flat; their tail is long, bony, and muscular; their wool has a silky appearance, but is harsh and wiry; and their flesh is much esteemed for its juiciness and flavour. The rams are singularly larger than the ewes and wethers; and they alone have horns,—which are very large, and lie close to the head, and project forward.

The old Wiltshire sheep formerly existed throughout most of Wiltshire, and in many other parts of the south of England; but they are now nearly extinct. They are large, coarse, and ungainly, and are very slow fatteners, and abound in properties which enlightened modern sheep-farmers reckon undesirable; but they have fine though scanty wool, and were therefore for a long time tolerated and even liked. Their head is large and coarse; their nose is arched and has been called Roman; their face and legs are white; their sides are flat; their limbs are long and thick; and their belly is destitute of wool. Both sexes are horned.

The Dorset sheep are a very ancient breed, and by far the best of the old horned varieties; and, though come down uncrossed from a very remote period, they maintain a high or rival place among some of the modern improved races.

They abound in Dorsetshire and in part of Wiltshire; and occur, in scattered flocks, throughout a large portion of Britain. Their body is tall and light; their faces are white, their legs long, and their wool short. Their shoulders are broad at the top, and lower than the hind quarters. The back is tolerably straight, the carcase deep, and the loins broad. The fleece seldom weighs above 3½ pounds; and the staple is not often more than two inches long. This breed is very prolific; and the ewes occasionally bring forth twice a-year. It is from them that the luxurious tables of London are supplied with Christmas lamb. The victims are reared in little dark cabins; and the ewes are kept in a neighbouring field, and fed with oil-cakes, corn, hay, &c., and introduced, after certain intervals, to give suck to their young. The latter are kept very warm and clean, and their lodgings are constantly littered with fresh straw. See the article Lamb. The wool of the Dorsetshire sheep, though not abundant, is of a superior quality, the fine Wiltshire cloths being fabricated from it.

The Somerset sheep are a subvariety of the Dorset breed. But they are larger and taller, and have more arched profiles, and have noses, not of a black or white colour, but of a pink or fleshy colour, similar to the Merinos. Their lambs also are larger, and their wool somewhat longer, yet of nearly the same fineness. Both the Somersets and the true Dorsets, however, have, for a considerable time past, been increasingly dislodged by the Southdown race from some of their grounds, and increasingly crossed and modified with them in others. Some or even many subvarieties of the same group as the Somersets and the Dorsets, were formerly more or less rife in the southern parts of England; but are now quite or nearly extinct.

The Portland sheep inhabit the Isle of Portland; and are cognate to the Dorsets, but are much smaller, and constitute a perfectly distinct breed, and have existed as such from an untraceably remote period. Both males and females have horns; and they have a good shape and a gentle disposition. Their face and legs are white, but have a tinge of dun; their wool is coarser than that of the Dorset, and makes a very light fleece; and their mutton is delicate and excellent, and fetches a good price in the market.

The Ryeland sheep took their name from a sandy tract of country, which was formerly used much for the raising of rye crops, in the valley of the Wye; but they have borne other names in the principal districts where they have prevailed,—and particularly that of Hereford sheep in most parts of Herefordshire, and that of Archenfied sheep or of Ross sheep in the tract of country situated between the Forest of Dean and the Malvern Hills. They are small and hornless; and have existed, as a distinct and unmixed breed, from a remote period; and have, for ages, been more or less cultivated throughout a large portion of Herefordshire, Monmouthshire, Gloucestershire, Shropshire, and Warwickshire, on account of the softness and fineness of their wool. "These sheep," says Spooner, "are of small compact forms, without horns, quiet in their habits, patient, and hardy. The mutton is delicate and juicy, and the carcase from 12 to 15 pounds per quarter. The wool is white, and extends over the face, and forms a tuft on the forehead. They are principally distinguished for the fineness of the wool, which is superior, for carding purposes, to all other of English produce, the Merino alone excepted. This formerly occasioned it to be in great demand, and to realize a good price; but since the general importation of the Merino wool, its great superiority has caused the demand for the Ryeland to be greatly diminished, and its price to fall in proportion. Thus the fleece being light, averaging only two pounds, it will not repay the trouble and expense that used to be incurred in keeping these sheep in large cots or houses, containing from 100 to 200, where they were fed with peastraw and dry forage,—a practice found to conduce very much to the fineness of the fleece, and which was generally practised when the Lemster wool, as it was termed from the city of Leominster where it was sold, was in the zenith of its prosperity." The Ryeland sheep, however, have been so extensively substituted by some of the larger races, and so generally modified, in places where they still exist, by old crosses with the Merinos, the Southdowns, and the Cotswolds, and by recent crossings with the Leicesters, that comparatively few of the pure breed now occur in even the districts where, at one time, they were most highly valued.

The black-faced or heath sheep are a very peculiar breed, and have a wild unreclaimed aspect, and inhabit lofty, heathy, barren mountainous tracts throughout the northern counties of England and in many parts of both the southern and the northern highlands of Scotland, from Dumfries-shire and Roxburghshire away even to the Pentland frith. It has existed from time immemorial in the north of England, and found its way many centuries ago into the south of Scotland; but was not introduced into the western, central, and southern highlands of Scotland till periods ranging downward from about the middle of last century, and has now, in a great measure, supplanted the earlier ovine inhabitants of these regions. "This breed," says Professor Low, "is of the smaller races of sheep with respect to the weight at which it arrives, but it is larger and more robust than the Shetland, the Welsh, and the ancient soft-woolled sheep which it displaced. It somewhat resembles the Persian, so that it might be conjectured that it is derived from the East. But it is more natural to assume that its peculiar characters have been communicated to it by the effects of food and

climate, in the rough heathy district from which it is derived. The male and the female have horns, very large and spirally twisted in the male, but sometimes disappearing in the female. The limbs are long and muscular, and the general form is robust; but the shoulders are not so low as in the Welsh breeds, nor are the posterior limbs so long. The face and legs are black, and there is a tendency to this colour in the fleece; but there is no tendency to the brown or russet colour, which distinguishes the older fine-woolled races. The fur is shaggy and the wool coarse, in which respect it differs from that of all the other mountain breeds of the country. It is of medium length, and weighs about three pounds the fleece when washed. These sheep are very hardy, and capable of subsisting on the coarsest heaths. They do not, however, like the sheep of Wales, prefer the summits of mountains, but feed wherever pasture can be obtained; and are not so nice in the choice of herbage as the Southdowns, Merinos, and other races derived from countries yielding the finer grasses. Although wild and independent in their habits, they are not so restless as the mountain sheep of Wales and other parts, but can be induced to remain in enclosures, when sufficient food is supplied to them. The ordinary weight of the wethers, when killed at the age of about four years, is 15 pounds the quarter; but individuals are made to exceed this weight, when properly treated and sufficiently fed from an early age. The mutton is not so delicate as that of the sheep of Wales, or the Southdowns of England; but it is more juicy, has more of the venison flavour, and is preferred to every other by those who are used to it. It is the mutton which is principally consumed in all the larger towns of Scotland; and great numbers of the sheep, at the age of three years and upwards, are carried to the pastures of the south, to be fattened for the English markets. An important property of this breed is its adaptation to a country of heaths, in which respect it excels every other. It is this property, as much as its hardiness, that has rendered it so suitable to the heathy mountains where it is acclimated, and where it finds subsistence beyond the ordinary range of other sheep. It feeds on the loftiest mountains, up to the very verge where the heaths give place to the musci and other plants of the higher latitudes. Feeding much on the shoots of heath, these sheep find subsistence, in the times of snow and severe frosts, better than any other in this country. The mothers are hardy nurses, and are able to bring up their young, when they themselves have been exposed to severe privations. A great defect of this breed is the character of the fleece, which, besides being thin on the body, yields wool fit only for the manufacture of carpets and the coarser stuffs. Little general attention has been paid to the quality of the fleece, although it is susceptible of considerable improvement. A defect of the wool, very common in this breed, is the existence of what are termed kemps. These consist of hard and wiry filaments mixed with the pile. They are deficient in the felting property, and in the oily secretion which moistens the true wool. The removal of kemps is effected by superior food, and by breeding from parents free from the defect." Some subvarieties of this breed deviate widely from the ordinary type; some are smaller and less hardy; some are hornless, and want the black colour of the face and legs; and some are degenerated, and others improved. The best are those of Peebles-shire; and among the next best are those of the most northerly parts of England. Some individuals have fine and short wool, and might easily be used for improving the fleece of entire flocks and subvarieties.

The Herdwick sheep are derived from a district of Cumberland round the head of the rivers Esk and Duddon. "The few farms where they are bred," says Bingley, "are called Herdwicks, that is, the district of the Herds, from the circumstance of the sheep having, from time immemorial, been there farmed out to herds at a certain sum per annum." They are hornless, with speckled faces and legs; and the wool is short. Those of the purest breed have only a few black spots on the face and legs. The fleece, which is thick and matted, seldom exceeds $2\frac{1}{2}$ pounds, and is among the coarsest of the short-woolled breeds. The Herdwick sheep are small, lively, and active, easily supporting themselves, even during the severest storms, by the quickness with which they scratch away the snow from the most scanty herbage. They are usually hornless; but Mr. Culley seems to think that they have been crossed by the Heath rams, from the circumstance of some of the males being furnished with horns, and from some 'kempy hairs' being usually intermingled with the wool.

The Cheviot sheep have existed from time immemorial on the grass-clad trappean mountains of the mutual borders of England and Scotland, and particularly on the porphyritic range from which they derive their name; and they have thence spread over the southern highlands of Scotland, and over large tracts of the central and the northern highlands,—in some places supplanting the black-faced heath sheep, and in others competing with them for popular favour. But though so near akin to that race, both in locality of origin and in territory of diffusion, they materially differ from them at once in character, habit, and adaptation; and while very profitably substituted for them on some pastures, have been just as unprofitably preferred to them on others. "The Cheviot sheep," says Professor Low, "are destitute of horns in the male and female. Their faces and legs are white, exceptions merely occurring in the case of individuals in which these parts are dun. The body is very closely covered with wool, which is short

and sufficiently fine for the making of certain cloths. The two shear-wethers, when fat, may weigh, on a medium, from 16 to 18 pounds the quarter, though with great differences, dependent on the natural productiveness of the pastures, and the method of treatment when young. The ewes are usually reckoned to weigh from 12 to 14 pounds the quarter, though with such differences as depend on the nature of the soil and pastures, and the method of treatment. The mutton of these sheep is very good, though inferior in delicacy to that of the Southdown and Welsh sheep, and in flavour to that of the black-faced heath breed. Their natural form is, like that of all mountain breeds, with a light fore-quarter; but this character is removed by the effects of breeding; and the modern Cheviots are of good form. The body is somewhat longer than is usually the case with the heath breed, which has given rise to the popular distinction, in districts where both breeds are cultivated, of long and short sheep. They are larger in the lower countries, where a supply of turnips can be given: they are lighter in the more elevated tracts, where artificial food is scanty or wanting. The breeders adopt the kind of animal which is suited to the pastures, preferring a short-legged larger sheep for the lower farms, and one of lighter and more agile form for the more upland and colder. The Cheviot sheep are of quiet habits, possessing, indeed, the independence of a mountain race, but having none of the indocility which distinguishes some other races. They are exceedingly hardy, their close covering of fine wool enabling them to resist the extremes of cold. They feed more on the grasses, and less on the shoots of heath, than the black-faced breed; and hence they are less adapted to a country of entire heath, and require a larger range of pastures to support an equal number of animals."

The Southdown sheep are indigenous in the downs of Sussex, or at least have existed there from a period antecedent to William the Conqueror, and are one of the purest and most unmixed breeds in Britain. They rank first among the short-woolled sheep, as the new Leicester do among the long-woolled sheep; and, are in pre-eminent request for all sorts of situations to which they are suited in England, and are also cultivated by many noblemen and other extensive landed proprietors both for the quality of their mutton and for their fine appearance in parks. They are most at home on such tracts as the South downs of England, whence they derive their name; and they have, to a considerable extent, supplanted the native races of Wiltshire, South Hampshire, Dorsetshire, Norfolk, and many other districts; and they have also been much used for modifying the native breeds by crossing in North Hampshire, Berkshire, Somersetshire, Cambridgeshire, and other counties; but they are not hardy enough to take the place of the black-faced heath sheep or the Cheviot sheep or the small Welsh sheep or other mountain breeds on the lofty and bleak uplands of the colder parts of the kingdom. Yet, till toward the end of last century, they were little known beyond their native walks in the South downs, and were marked by the undesirable characteristics of a thin chine, a low fore-end, and a rising back-bone; and they were first improved and brought into general notice by the late Mr. John Ellman of Glynde in Sussex, who commenced a course of skilful, perspicacious, and most successful experimenting upon them about the year 1780, and conducted it, with slow and steady effect, during the long period of more than fifty years. Mr. Ellman's own account of an improved South down sheep, except that no spot or speckling on the face can now be endured by good breeders, is still the best description which can be given of the breed:—"The head small and hornless; the face speckled or grey, and neither too long nor too short; the lips thin, and the space between the nose and eyes narrow; the under jaw or chop fine and thin; the ears tolerably wide, and well covered with wool, and the forehead also, and the whole space between the ears, well protected by it, as a defence against the fly; the eye full and bright, but not prominent; the orbit of the eye (the eye-cap or bone) not too projecting, that it may not form a fatal obstacle in lambing; the neck of a medium length, thin towards the head, but enlarging towards the shoulders, where it should be broad and high, and straight in its whole course above and below; the breast should be wide, deep, and projecting forwards between the fore-legs, indicating a good constitution and a disposition to thrive. Corresponding with this the shoulders should be on a level with the back, and not too wide above; they should bow outwards from the top to the breast, indicating a springing rib beneath and leaving room for it; the ribs coming out horizontally from the spine and extending far backward, and the last rib projecting more than the others; the back flat from the shoulders to the setting on of the tail; the loin broad and flat; the rump long and broad; and the tail set on high and nearly on a level with the spine; the hips wide; the space between them and the last rib on either side as narrow as possible, and the ribs, generally presenting a circular form like a barrel; the belly as straight as the back; the legs neither too long nor too short; the forelegs straight from the breast to the foot, not bending in at the knee, and standing far apart both before and behind; the hocks having a direction rather outward, and the twist, or the meeting of the thighs behind being particularly full, the bones fine, yet having no appearance of weakness, and the legs of a dark colour; the belly well defended with wool, and the wool coming down before and behind to the knee and to the hock; the wool short, close, curled, and fine, and free from spiry

projecting fibres." A new and beautiful subvariety of this breed, known as the Babraham Southdowns, was recently raised by Mr. James Webb of Babraham in Cambridgeshire, and has come into great favour.

The Hampshire Down sheep cannot easily be traced to their origin, and seem not to have had any existence till about 60 or 70 years ago. The original sheep of the downs of Hampshire were a large, hardy, long-horned, coarse-boned, unthrifty breed, with tolerably fine short wool, good milkers, and similar in many respects to the old Wiltshire breed; but they are now extinct. The present race seem to have had a mixed origin, and probably arose, in a main degree, from crosses of many of the earliest rams of the improved Southdown race with ewes of the old Hampshire and the old Berkshire races; and they have a larger bulk, a stouter structure, coarser bones, and longer legs than the present Southdowns, and are better adapted for enduring hardships, and for serving some general purposes. The normal form of this breed prevails in North Hampshire; a subvariety of it extends into Berkshire and Wiltshire; and a mixture of it and the Southdown, with a predominance of the blood of the latter, prevails in South Hampshire.

The Lincoln sheep are a long-woolled race, but comprise two very distinct breeds, the old and the improved. The old Lincoln sheep are the most remarkable of the peculiar, coarse, large-bodied family who inhabit the rich marshy tracts of the Fens of England. They are hornless and whitefaced, and have a large tuft on their forehead; their size is bulky, their form coarse, and their bones large; their legs are large and rough; their flanks are hollow, their sides flat, and their carcases thin and weak; their fleece is wondrously heavy, and sends down its long unctuous wool in pendulous masses almost to the ground; and their flesh is coarser, leaner, and less finely flavoured than that of the smaller breeds. But they fatten slowly, and consume much food, and are ill adapted to any system of sparce or artificial feeding; and now they occur within narrow limits, and are hastening to extinction. The improved Lincolns are a cross between the old Lincolns and the Leicesters, and are smaller than the former, and have less wool, and a better form, and a greater aptitude to fatten, and a superior thriftiness of growth, and a better adaptation in every way to the altered circumstances of the husbandry of the plains. "With the new era of agricultural improvement, when the heaths, wolds, and rabbit warrens were converted by the spirited breeders into tillage, arose the great importance of adapting the large unwieldy old Lincolns, hitherto produced for the rich marshes, to the more moderate production of the healthy soils under improvement; consequently rapid advances have been made in their improvement by judicious crosses with the Leicesters; and at the present time they rank amongst the most valuable breeds for the purposes assigned to them, and are shown in great perfection at the great spring fairs of Lincoln, Caistor, Boston, and other places, at each of which full 20,000 lamb-hogs usually change hands, from the heath and wold breeders to the graziers and dealers from the surrounding grazing districts. But they are principally shown in condition for the butcher; and, instead of representing the old coarse breed to be fattened when 2 or 3 years old, they now combine to a great extent the properties of the Leicester, upon a larger scale, with a longer and heavier staple of wool; and in this they have been much aided by the judicious selection of males, from time to time, by the spirited ram-breeders in the different districts in the county."

The Romney marsh or Kent sheep inhabit the low flat extensive fen district on the south coast of Kent, and have extended thence into other parts of that county. The old or native breed were coarsely-shaped long-woolled animals of similar character to the old Lincolns, but smaller. Their head was coarse, and had a tuft of wool; their neck was thick; their chest was narrow; their sides flat, and their bellies large; their limbs were long and stout, and rested on broad feet; and their fleece weighed 7 lb. or 8 lb., and had wool of different qualities on different parts, but in the aggregate moderately soft. They fattened slowly, and, though well liked by the butcher, were unthrifty to the farmer, and consequently passed, in the progress of modern improvement, into general disfavour. The modern breed is a very diversified cross between the old breed and the Leicester; and while some flocks of it exhibit much of the character of the old, and have long legs, flat sides, and coarse extremities, other flocks exhibit scarcely a trace of it, and possess an independent character of much improvement in form, greater disposition to fatten, superior thriftiness in growth, and considerable reduction in size. "Though the pure Leicester ram," we are told, "is now but rarely employed, from the fear of inducing a too great delicacy in the breed, and an inability to withstand the exposure to the weather, and the absence of shelter; yet the present race evidently shows the source from whence it derived its improvement. With the progress of this improvement also there arose a greater disposition to select the most improved specimens for the perpetuation of the race; and the adoption of this principle has, in a great measure, prevented the necessity of returning to the pure Leicester."

The Bampton Notts or Devon sheep are a recently established and very fine breed of long-woolled animals, formed by crossing an old breed on the confines of Devonshire and Somersetshire with the Leicester sheep. The old breed had a white face, a coarse clumsy form, a thick hide, and a long and heavy fleece; and, though difficult to fatten, they weighed at two years of age

from 30 lb. to 35 lb. per quarter. They were called Bampton Notts, from the village of Bampton, and in contradistinction to a race of small-bodied, brown-faced, flat-sided, crooked-legged animals in their vicinity, who bore the name of Southam Notts. The present breed are quite free from all the characteristic defects of the old; and though diminished in bulk, are still among the largest sheep in Britain. The farmers of Devonshire are proud of them, and seem to like them all the better for their comparatively great size.

The Cotswold or Gloucester sheep inhabit the Cotswold hills in the eastern part of Gloucestershire. They are a stationary or retrograde cross between an old breed of the same district and the new Leicester. But whether that old breed were originally long-woolled or short-woolled, and whether they became known at a comparatively recent period or inhabited the Cotswold hills from a very remote date, are matters of dispute. Some persons even imagine that they were the origin of the Merino sheep; and others strongly suppose them to have been introduced at no earlier a period than some time in the course of the last century. But whatever were their previous history, the immediate ancestors of the present breed are known to have been larger in body and coarser in form than they, and are said also to have borne a greater weight of wool. The crossing of them with the new Leicesters began about 60 or 65 years ago, and was steadily and sweepingly prosecuted till not an individual could be found unmodified by the Leicester blood. But after a lapse of 30 or 40 years, "the Cotswold breeders began to apprehend that their flocks were losing too much in carcase and fleece, and becoming less fitted for the climate of their native hills; and from that period, a preference began to be given to the native stock; and for many years past, crossing has been scarcely practised, and most of the breeders have been desirous to revert more to the former model of their breed." The present Cotswold sheep are somewhat larger in size, and have the wool closer on the body, than the highest bred new Leicesters; and they are hardier, more prolific, better milkers, and more amply adapted to common treatment; and therefore have they, in many places, become the successful rivals of the Leicesters, both for constituting entire stocks and for crossing with other breeds.

The new Oxford sheep, or improved Oxford sheep, are simply the best or most refined subvariety of the modern Cotswolds, and differ from the Gloucestershire subvarieties mainly in having flesh of a firmer consistency and a finer texture. "They are bred principally in Oxfordshire and the surrounding districts,—particularly in the neighbourhood of Broadwell, Charlbury, and Sevenhampton. They are of large dimensions, and have a great propensity to fatten, arising chiefly from their wide frame, quietude, and open texture of flesh, which is of quick growth, and consequently expands itself more rapidly than many other qualities; but they do not possess that exactness of form peculiar to smaller animals, though they have a better carriage. For many years, the male animals have been eagerly sought after, with a view to increase the size and frame of other long-woolled breeds."

The new Leicester or the Dishley sheep originated in a series of systematic experiments, begun about the year 1755, and conducted by Robert Bakewell of Dishley in Leicestershire. What old breeds he used in these experiments, and in what proportions he employed them, or whether he used some permanently and others transiently, or some predominantly and others subordinately, are matters of mere conjecture and much dispute. He chose to be mysterious; and he managed to make all the sources of his experiments a perpetual secret. The old Leicester breed, who might come most readily to his hand, were large coarse animals, with an abundant fleece and a fair disposition to fatten,—and they possibly contributed not a little to his results; but other long-woolled breeds, particularly the old Lincoln, and two extinct races in respectively Warwickshire and the valley of the Tees, are also conjectured to have been more or less in requisition; and even breeds of widely different characters, especially the Ryeland, the Southdown, and some other short-woolled races, may possibly have lent their aid. But though Bakewell's subjects are conjectural, both the principles on which he worked them into a new breed, and the practices by which he rendered the breed distinct and permanent, are well known. "He perfectly understood," says Professor Low, "the relation which exists between the external form of an animal and its aptitude to become fat in a short time. He saw that this relation did not depend upon size, nor, in the case of the sheep, on the power of the individual to yield a large quantity of wool. He therefore departed from the practice of all former breeders of the long-woolled sheep, who had regarded size and abundant growth of wool as primary properties in the parents. Holding bulk of body, and the produce of the fleece, to be secondary properties, Bakewell directed especial attention to the external form which indicates the property of yielding the largest quantity of muscle and fat, with the least bone and what is usually termed offal. He aimed, too, it is said, at producing the fat on the most valuable parts; but this is merely a subsidiary property, dependent upon general harmony of conformation. Progressively perfecting his animals by skilful selection, he necessarily continued to breed from his own stock, and did not scruple to connect together animals the nearest allied in blood to one another. This system, continually pursued, not only gave a permanency to the characters imprinted on his sheep, constituting a breed, in

the proper sense of the term, but tended to produce that delicacy of form, which experience shows to be connected with the power of secreting fat, and arriving at early maturity, or what may be termed premature age. The system, acted upon for successive generations, tended likewise to render the animals more the creatures of an artificial condition, more delicate in temperament as well as in form, less prolific of lambs, and less capable of supplying milk to their offspring. It cannot be supposed that Bakewell was unobservant of these effects; but he appears to have regarded them as being of a consideration secondary to the property of producing, in the shortest time, the largest quantity of fat, with the least consumption of herbage and other food. That this was the main result at which he aimed, all his practice shows; and his success corresponded with the skill and perseverance with which he applied his principles to practice. His stock became gradually known and appreciated in the country around him; but it was not until after the lapse of nearly a quarter of a century, that it arrived at that general estimation in which it was afterwards held. He early conceived the idea of letting his rams for the season, in place of selling them. The plan was ridiculed and opposed in every way; and it was not until after the labour of many years, that he succeeded in establishing it as a regular system. It is said that his rams were first let, in 1760, at 17s. 6d. each; but this was certainly before his breed had arrived at its ultimate perfection. His usual price afterwards became a guinea, and, in rarer cases, two or three; but the price rapidly advanced with the increasing reputation of his stock. In 1784–5, the price had risen to about 100 guineas for his best rams; in 1786, he made about 1,000 guineas by the letting of his stock; and in 1789, he made 1,200 guineas by three rams, and 2,000 guineas by seven; and in the same year, he made 3,000 guineas more by letting the remainder of his rams to the Dishley Society, then instituted."

The best form of a Leicester ram—according to the description of Mr. Culley, who was one of the earliest and most successful of Mr. Bakewell's followers in the breeding of the new race—is as follows:—His head should be fine and small; his nostrils wide and expanded; his eyes prominent, and rather bold and daring; his ears thin; his collar full from his breast and shoulders, but tapering gradually all the way to where the head and neck join, which should be very fine and graceful, being perfectly free from any coarse leather hanging down; the shoulders broad and full, and at the same time joining so easy to the collar forward and chine backward, as to leave not the least hollow in either place; the mutton upon his arm or fore-thigh must come quite to the knee; his legs upright, with a clear fine bone, being equally clear from superfluous skin and coarse hairy wool, from the knees and hock downwards; the breast broad and well forward, which will keep his fore-legs at a proper wideness; his girth or chest full and deep; and, instead of a hollow behind the shoulders, that part, by some called the fore-flank, should be quite full; the back and loins broad, flat, and straight, from which the ribs must rise with a fine circular arch; his belly straight; the quarters long and full, with the mutton quite down to the hock, which should neither stand in nor out; his twist deep, wide, and full, which, with the broad breast, will keep his fore-legs open and upright; the whole body covered with thin pelt, and that with fine, bright, soft wool. We shall add the characters of Mr. Bakewell's ewes and wedders, which are supposed to have surpassed all others in beauty of form. The head is long, small, and hornless, with ears somewhat long, and standing backwards, and with the nose shooting forward; the neck thin and clean towards the head, but taking a conical form, standing low, and enlarging every way at the base; the fore-bend altogether short, the bosom broad, with the shoulders, ribs, and chine extraordinarily full; the loin broad, and the back bare; the haunches comparatively full towards the hips, but light downwards, being altogether small in proportion to the fore-parts; the legs of moderate length, with the bone extremely fine; the bone throughout remarkably light. The carcase, when fully fat, takes a remarkable form, much wider than it is deep, and almost as broad as it is long, full on the shoulder, widest on the ribs, narrowing with a regular curve towards the tail, and approaching somewhat the form of a turtle; the pelt is thin, and the tail small; the wool is shorter than long wools in general, but much longer than the middle wools, the ordinary length of staple from 5 to 7 inches, varying much in fineness and weight.

The new Leicester breed is, in an aggregate view, better or more perfect than any of the other races of long-woolled sheep; and it has abundantly proved itself capable of imparting some improvement to every one of them by crossing, and at the same time has derived no advantage from any in return, but can be maintained in vigour only by being kept pure, and perpetuated from the best of its own stock. New Leicester sheep, as regards their feeding qualities, are more profitable on rich low pastures than any other sheep whatever; they come earlier to maturity than even the Southdowns,—a new Leicester wether being fat at 22 months, while a Southdown one is seldom as far forward till he becomes a twelvemonth older; and they contain in their carcase a greater amount of dead weight in proportion to the amount of live weight than any other breed,—the flesh and fat being accumulated more externally, and in the greatest degree in the most profitable parts, and in the least degree in the coarse points. Some of the chief disadvantages of the breed, as compared with the characters and properties of other good

breeds, are inferior prolificity, feeble nursing powers, deficiency in bulk of fleece, comparative weakness of constitution, predisposition to inflammatory diseases, and inability to bear exposure to a churlish climate or to inclement weather. These defects, however, are less now than in the days of Bakewell; and, whenever purity of breed is not an object, they can be much reduced or almost entirely overcome by crossing with such other breeds as the Cotswold and the Bampton Notts. "Bakewell was compelled, in a sense, to confine himself to his own stock, and to the blood of one family, in order to preserve that standard of form which he had produced; but from the subsequent multiplication of the new Leicester breed, modern breeders are relieved from all necessity of this kind. They can obtain individuals of the form required from different flocks of the same breed, and need never, by a continued adherence to the blood of one family, produce animals too delicate in form, deficient in weight of wool, and in that hardiness and soundness of constitution, which are even more necessary than the perfectness of individual form, for the safety and profit of the breeder. The sacrifice of the secondary properties which Bakewell did not hesitate to make, was the result of circumstances which do not now exist; and the present feeling of the breeders is to maintain a larger and more robust form of the animals than seemed good to the earlier improvers. Thus, the Cotswold breed of sheep, though far inferior in form to the pure new Leicester, is maintaining a successful rivalship with it over a large extent of country; the lowland Gloucestershire, the Devonshire, and many of the Lincolnshire agriculturists, are propagating a larger race than is approved of by the Leicester breeders; and even in the north of England, where the Leicester breed was early established, a heavier race is preferred to the purest of the Dishley stock."

The Management of Sheep.—Some of the general and most important points in the right management of all or most kinds of domesticated sheep are discussed in the articles Food of Animals, Feeding, Fattening, Fold, Hurdle, Turnip, Grass-Lands, Pasture, Breeding, Crossing, Bathing, Washing, and Shearing; and other points in the right management of groups or classes of breeds are noticed in the articles Salving, Rot, Braxy, Scab, and Fly-in-Sheep. The best special management of some of the hardiest or least improved breeds is either so simple or so much beyond the control of advice, as not to require any mention; and that of the breeds most generally cultivated in either the uplands or the plains of good sheep districts, though varied according to the habits of the several breeds, and diversified in adaptation to differences of circumstances and of design, and though subject, in most instances, to considerable conflict of opinion or variation of practice among both eminent scientific agriculturists and intelligent, experienced, practical farmers, yet does not require to be detailed in the case of each breed, or with reference to each class of climates and circumstances, but may be sufficiently indicated by short specimen instances to enable any tolerably reflecting young farmer to infer all the details which may be most proper for his flock and farm. The specimen instances which we shall select have reference to the Black-faced, the Southdown, the Lincoln, the Cotswold, and the Leicester breeds.

The black-faced sheep of most districts are merely reared on their native pastures, and then sold to farmers in lower situations who keep them till the age for fattening, and then sold to graziers and farmers on the plains or in the valleys who prepare them for the butcher by means of rich grass lands and artificial food. The ewes receive the rams about the latter part of November; so that the lambs are not dropped till the season becomes open and mild. The flocks are sometimes overwhelmed by severe snow storms; yet they usually receive no artificial supplies of food on their lofty, bleak, sparce pastures than a little coarse hay, sparingly given them at times when they cannot possibly find access to the natural herbage. The ewes are often very weak at the lambing season; and yet they support their lambs well. About the beginning of July, all the full-grown sheep are made to wash themselves by leaping into a stream or pond and swimming to the opposite bank; and, in a few days after, they are shorn; and in the end of October or the beginning of November, they are smeared or salved. On some farms, all the young sheep, while in the state of hoggs, except such as may be wanted to supply the place of the old ewes, are sold; and on others, they are kept till they arrive at two or three years of age. In some farms, also, particularly in somewhat low-lying districts, or with considerable intermixtures of good meadow or arable land, the supplies of artificial food and the alleviations of suffering from the severity of the weather, are far ampler than in the great majority of mountain farms. The winner of a premium at the Edinburgh wool competition in 1845, reports as follows respecting his treatment on a farm in the vicinity of Moffat, of from 910 to 1,550 feet of altitude above the level of the sea, and whose lower parts are enclosed, well-sheltered, and arable: "For the greater part of the year, the sheep are entirely confined to the upper division, or steep ground. The pasture is short and of a bright colour, intermixed with coarse bent, which requires to be burnt in spring. Some years ago, part of the benty ground was ploughed, heavily limed, and sown with grass seed; and thus a great improvement was effected, the bent having been replaced by a bright green pasturage, which cannot be distinguished from those portions of the ground that are not naturally covered with

bent. In winter and spring, the sheep, if their condition seems to demand it, are admitted into such of the lower parks as have been cut for hay, or pastured during the summer by the dairy stock, which is then fed in the house. The sheep are let down from the higher ground in the morning, but are invariably put out of the parks between one and two o'clock in the afternoon. In the event of a severe snow-storm, they are fed with meadow-hay, which is carried out to them. In weaning the ewe-lambs intended for stock, they are put into one of the parks for a week, and then allowed to return to their mothers, whom they recognise, but no longer attempt to suck. An advantage of this plan is, that the lambs follow their dams through the winter, and, if there is snow, they are helped by them to scrape, so that they do not so often need to be fed with hay as when they are kept separate all the winter."

The management of the Southdowns varies with the nature of the district or farm, with the size of the flock, with the subvariety or quality of the sheep, and with the resources or particular husbandry system of the owner. On the true down farms, not only in Sussex, but in Hampshire, Wiltshire, and Dorsetshire, the old practice was to keep them almost wholly on the hill pastures during the day-time throughout the greater part of the year, and to fold them on the arable land at night, and give them there an allowance of hay, at least in the months of winter, and sometimes in most months of the year; and the newer practice, after the introduction of the turnip husbandry, and the consequent enlargement of the flocks correspondingly to the increased supply of winter food, was to treat the old sheep in the same way as before, and to devote the turnips to the support and the prolonged feeding of the young sheep; and the expedients for meeting the common exigency of the exhaustion of the turnips by about mid-winter or the destruction of the remains of them by the frosts of January, previous to the period when the Swedish turnip was brought into cultivation, were, in general, either to make reservations of autumnal grass in the manner of 'fogging,' or to find large supplies of hay, or to regulate or diminish the size of the flocks according to the prospects of spring-feed. The practices of the present day are necessarily far more diversified, and range from an imitation of the old system, or from the mere giving of hay in winter and a few Swedes after lambing, to almost any degree of complication arising out of the improved systems of mixed and rotational husbandry, particularly in the supply of artificial green food for both winter and summer, and of several valuable and prolific kinds of winter-growing crops for spring-feed. The most common artificial supplies, in aid of the native pastures, or in joint-use with them, or in substitution of them, are sown grasses, tares, vetches, turnips, Swedes, mangel-wurzel, cole, rye, and mustard. But, in all the native upland districts and characteristic pasturing-grounds of the Southdowns, they continue to be appropriated specially to downs, heaths, and thin arable soils, and are still more or less dependent, throughout a great part of the year, on the scanty produce of these sheep-walks; and they are, in consequence, treated from lambing-time onward in methods of peculiar adaptation to the circumstances of the farm or district. "In these situations, they are sent regularly to fold, with the exception of those put out for fattening. It was originally the plan to keep the wether sheep with the general flock, and allow them to go to fold until drafted for the London market; more recently they have been divided, and fed at a much earlier age,—many are fatted at the age of 16 or 18 months. With some breeders, who have good meadows and other advantages, the ewes and lambs are not allowed to go to fold, their system being to force their lambs forward for the September fairs, when they fetch exceedingly high prices; others under less favourable circumstances send them to fold regularly, and sell their lambs in a lean state at the same period, that being the season at which the great transfer between the breeders and feeders takes place. Of late years, they have also found their way into the more distant counties to be fatted upon the turnip-soils. The ewe trade has also materially increased, they being sought after for the purpose of crossing with the Leicester or other long-wools; they are then included with the general flock, rarely or never being sent to fold, and they make great improvement. When mixed with other breeds, they are found to produce more lambs, and give more support to them, but to produce less value of wool and to consume more food."

The management of the Lincoln sheep is very much diversified and complicated, and varies according to the subvariety, the district, the general design, the special husbandry, and some particular circumstances. The mode of feeding and fattening the store-flocks depends entirely upon the soil and situation in which they are kept. No breed of sheep vary more in their character and management, from the circumstance of their being bred to suit the marsh-land or the arable districts. The flocks suited to the former districts are most commonly bred in the north and north-eastern parts of the county, and possess more the character of the old style of Lincolns. The breeders of this description of sheep make it their study, in setting their flocks, to select those females that possess the longest wool, strong bone, and largest size, their leading object being to raise a thick-fleshed, hardy animal, suitable to their soil and climate, which, from its coldness during the spring months, is only considered suitable for lambs coming rather late in the season. Their plan of management during the lambing season

varies but slightly from the Leicester, with the exception of their having good grass reserved to place them upon after lambing. The lambs are allowed to remain with the ewes until the 1st of August; and they are then placed upon clover eddish, and subsequently upon coleseed, and are finished with cut swedes. Corn is rarely given in this district. The study of the breeders is to turn out large long-woolled lamb-hogs for the purpose of grazing, when, unless sold to the graziers, they are run very thickly upon their clovers, or middle descriptions of grass-land, during the summer. From the bleakness of the district, they are not shorn until the beginning of July; and, as these breeders and graziers look more to quantity than quality of wool, it suits their system. During the month of August, the flocks are thinned out to other parts of the farm; and afterwards they are placed in their winter-quarters on the best grass-land for fattening. When they are intended to be sold in March or April, they are allowed from half a pint to a pint of old beans per day, that kind of food being best in their cold situations. On the rich or warmer lands, they attain a sufficient degree of fatness without any artificial food, and are also sold off about May. With the graziers they are replaced with lamb-hogs at the late fairs, which is an excellent arrangement. Those shearlings that have been kept back upon the second-rate grass-lands are put forward amongst the beasts on their rich pastures during the summer; thence they go to coleseed, and subsequently they are sold to the butchers in the neighbourhood, being far too heavy for the London trade, as at this period of the year they weigh from 30 to 36 lbs. per quarter upon an average. The sheep bred upon the heath and in the middle of the county are the improved Lincolns; and their management is closely assimilated to the Leicester, particularly upon the heaths near Lincoln. With the addition of their spirited husbandry in supplying them with artificial food throughout the year, the universal plan of these breeders is to sell their lamb-hogs in the spring from turnips; consequently every movement is brought to bear upon the production of first-rate fat lamb-hogs, whereby an immense return is made in the shape of wool and mutton, as also in the succeeding crops of barley, seeds, and wheat. The effect of sheep-husbandry on the productiveness of the soil is an important feature in the general rules laid down upon the heath-farms; for, as the soil requires artificial aid, so does the importance of producing sheep at an early age become essential. By constant attention to an equal and proper distribution of the flock fed upon artificial food, immense results follow, it being better to spend a portion of the money set aside for artificial manure in the purchase of oil-cake, &c., to be passed through an animal to the soil, thereby gaining a second return, than to expend the whole amount in the production of vegetables. Again, such are the propensities of the best sheep to fatten, that an ample return of wool and mutton is made for the extra keeping allowed them, and the land is manured at a cheap and easy rate. Further, by the use of artificial food, the vegetable produce is much economized, the animal is kept longer upon the land, and becomes more healthy and less liable to disease. The breeders upon the heaths and wolds rarely occupy grass land, but generally plough their whole farm, and merely procure a portion of marsh land at a distance and use it for growing or feeding the cattle raised on their ploughed farm. In setting their flocks at Michaelmas, they select ewes who are uniform in size, frame, fleece, and style, and use only rams who, in addition to being well-proportioned, possess what they call 'good looks;' and during the lambing season, some of them feed their ewes upon mangel-wurzel, and find it to suit much better than turnips. The wether-lambs of the principal breeders are preferred to the ewe-lambs, and separated from them at an early period; and when taken off about the middle of July, they are still supplied with corn or oil-cake upon the seeds; and afterwards are placed upon the turnips; and, in the barley-thrashing season, are indulged with bruised barley and malt-comb along with oil-cake; and as the spring advances, receive cut swedes in addition to other artificial food. Some breeders prefer keeping their lamb-hogs until the late fairs, and allow them to take the best of their young seeds; others reserve them entire for the ewes that are suckling the couples and wether-lambs. In some instances, the lambs are not castrated until the first week in August, to produce extra size and constitution, when they are either castrated, or what is termed "trapped," and are rarely known to falter or decline eating their food after the operation. The ewe-lambs are drafted early in the winter, and the culls placed with the wether-lambs to be sold in the spring,—the best being reserved for the flock, and kept entirely upon turnips. The flock-ewes are inspected and drafted early in the summer, and are removed from their lambs about the first week in June, when they are prepared for the autumn fairs, and fetch high prices, breeders from the surrounding districts being anxious to procure them. In the southern or Grantham district, the wether-lambs are kept upon moderate food during the winter, it being the practice to sell them as shearlings in the autumn, when they are purchased by the graziers for wintering upon their grass-land, or for feeding off coleseed, where the land is intended to be sown with wheat.

The Cotswold sheep are kept principally on the hills and on circumjacent poor, thin-soiled, arable tracts; and they require to be managed on principles of good sheep-husbandry. The breeders produce their sheep at an early age; and the best flock-masters rarely practise fold-

ing. In setting the flocks, particular attention is paid to size, wool, strength of constitution, propensity to fatten, and uniformity of character and carriage, by which the animals are easily distinguished from other long-woolled breeds. The ewes are placed with the ram rather early in the season; and care is taken to have a reserve of fresh keep to remove them to about the middle of September. The rams are continued with the ewes about nine weeks; and during the latter part of this time, they are kept upon white turnips, and thence they are drawn out weekly upon the plan adopted by the Leicester breeds. Great attention is paid to the flocks during lambing-time, the yards being made very warm and comfortable. The wether-lambs are put forward and managed upon a similar plan to those upon Lincoln Heath; but the Cotswold breeders are more particular in having early spring feed for them. They are supplied with corn, according to circumstances, through the summer. When the clovers are going off about midsummer, they are frequently removed to green tares provided for them, the ewes being taken away and placed in some distant field. When the lambs are placed upon the tares, they are either allowed fresh pens from time to time, as they require them, or the tares are mown and given them in racks, or laid alongside the trays to be eaten through them. The better plan, when consumed upon the land, is to have a regular set of iron trays, upon feet, coupled together by rings and staples. These trays should be 12 feet long, upon oak feet 2½ feet long, which may be moved in an onward direction several times a day, according to the consumption through them. By this plan the tares are much economized, and fed off without being in the least degree soiled. These iron trays, being portable, are equally good for feeding off coleseed upon the same principle, and are much used for this purpose in South Lincolnshire, where it is not uncommon to see coleseed much higher than the sheep, particularly in those situations where paring and burning is practised, and the seed drilled in with a portion of bones. When the feeding of tares is practised to any extent, they are sown at different intervals during the spring, to hold out until after harvest, at which time the lambs are removed to the barley stubbles, or young seeds, and are supplied with white turnips thrown upon the land for a short time. They are placed upon the turnips at the end of September, and commence their winter management with cut turnips and artificial food, which is increased during the winter. About March and April, they are sold fat to the butchers in the neighbourhood, or sent to the London market. Those breeders who bestow less care and expense upon their lamb-hogs, sell them in a store state at the principal fairs in the neighbourhood, to be fattened by the graziers. The breeders, in fact, make it their practice to clear them off when the turnips are finished. The flock-ewes are drafted and sold upon the plan adopted by the Lincoln-Heath breeders.

The new Leicester sheep require to be reproduced on principles which will secure the purity of the breed, and promote, in the surest way, the prolificity of the ewe. All the best breeders are very fastidious about the sound blood and the good points of both rams and ewes, and promptly reject animals who, though otherwise exceedingly good, possess some little deteriorating cross or deteriorating tendency, or want some little uniformity in their general outline; and some reject the entire produce of any ewe or set of ewes who have in any degree disappointed them, and are exceedingly cautious in using young sheep who have not been proved, preferring to see their produce in order that they may proceed with the least possible risk of defect. Ewes who have been selected for breeding are, for some time, kept in better fare than the rest; and groups or classes of them are studiously assigned to such rams as are best suited to correct their faults. The method of many breeders is to admit the rams early in September for forward lambs, and about the first of October for the general stock of lambs; but a much better one, now generally practised by the most successful breeders, is to place "a teazer" with the ewes, and to bring them individually and regularly out as they are observed. When the office of the ram is over, the ewes are dressed with mercurial ointment, in the proportion of 2 lbs. to the score, to cleanse them and to assist the growth of the wool. On grazing farms, the ewes, up to this season, and in many situations much longer, are kept upon the grass or meadow lands; but on arable farms, which contain but a small proportion of grass land, they are usually placed upon the turnip lands, to pick up the leavings of the store-lambs, who are allowed to go forward,—and they do exceedingly well. But a fortnight or so before lambing, they are drawn out and placed upon grass land, if possible, near home; they are shut up every night in a lambing-yard; a few turnips are thrown to them in the field when convenient, otherwise they are allowed a moderate quantity of corn, with cut hay or clover chaff; and when suitable, they are placed upon turnip-lands for a few hours during the day, exercise being very desirable. Those that have lambed during the day or night are removed to convenient sheds previously prepared for the occasion, and thence to better quarters, such as a prepared field of rye, or rye and tares mixed with a little coleseed, but more commonly to young seeds or grass-lands which have been rested for them, and there supplied with a few turnips or corn. Upon arable farms, it is frequently their lot to be again placed upon the turnip-land, with a supply of rock-salt to lick in small iron troughs. Salt is also frequently given with the chaff. In those situations where the

breeder has no arable land, which is the case on a great many farms in Leicestershire, the ewes are placed with the ram at a comparatively late period in the season; and are fed entirely, or almost entirely, upon grass throughout the year. It would be better, however, to supply them with a moderate quantity of corn during the spring or lambing-season, as they are then frequently so much reduced, as to cause great loss during the lambing-time, besides stinting the quantity and quality of wool, and occasionally making the dam, offspring, and fleece, all culls. In the case of a ewe losing her lamb, it is customary to place the skin of her offspring upon another lamb intended to be put with her; and the ewe generally takes to the stranger in a short time; but in the event of difficulty, a little gin rubbed upon the skin of the lamb and nose of the ewe at once effects the desired object. Upon turnip and seed-farms, where the design is to raise fat wether lamb-hogs, the management of the lambs is commenced at an early period. They are promoted in regular succession, being first separated from the ewe-lambs and allowed to take precedence throughout the year. It is now the practice to wash and shear the general flocks in the beginning of June; though this is considered by some too early in the season. By this plan, they are found less subject to fly-galls, gain more weight during the summer, and have a more bulky appearance when sold in the autumn; and there is no difference in the weight of wool, if adopted as a general system. The custom of dipping the lambs directly after the ewes are shorn is a valuable one, and should never be omitted. There is also a growing practice of having the whole flock dipped at this period of the year, as it affords an excellent opportunity for cleansing them. The lambs are again dressed with mercurial ointment in the first week of October; if this be omitted, they are much tormented during the warm spring months. The weaning of lambs is considered to be a nice point, as much depends upon its being properly accomplished. The plan of taking the ewes from their lambs to a distant field reserved for them, rather than taking the lambs from the ewes, is preferred; for the lambs being accustomed to their pasture, remain more quiet than when removed to a strange field, where they fret, become thin and exhausted with bleating, and too often incur fever and scouring, which are the forerunners of other diseases, and the cause of their doing badly for weeks, if not the whole winter following. The ram-lambs are put with their dams into the clover or reserved spots for some few days previously to weaning, where they learn to eat green tares, which are found invaluable by those breeders who use them for a start. Lambs should never be placed upon rested summer-eaten clover pastures, however tempting they may appear, as they invariably cause scouring, fever, and other severe ailments. Old grass, clover, or grass-eddish is preferable until the autumn quarter commences, which is considered an important one, as much depends upon the manner in which the lambs are started, or taught to eat their winter food. In the middle of September, the lambs are placed in moderate lots upon grass or seeds, as, from the domestic habits peculiar to the race, they are fond of picking their food at this season of the year, cabbages being thrown to them upon the pastures, or cut for them in troughs; and after a short time, a few white turnips are mixed with them, as a preparation for the winter. As October advances, they are placed upon the common or white turnips. Some breeders mix a little coleseed in the first sowing, and find it an excellent plan. After a short time, the wether-lambs receive each $\frac{1}{4}$ lb. of oil-cake, or corn to that value, per day; and at Christmas, they are placed upon the swedes which are cut for them,—as are also the white ones upon bad layer. As the spring advances, the oil-cake or corn is increased according to circumstances, whether the animals be intended at once for the butcher, or are to be kept until midsummer, or even later. The ewe-hogs are kept entirely upon turnips and cut clover-chaff, with plenty of salt. When the turnips are finished, the ewe-hogs are placed upon moderate grass-land or old seeds. When the wether-lambs are reserved for fat shearlings, they are placed upon the young clovers to commence their work, and are sold by some breeders about August or September, to make room for the lambs. Other breeders prefer to keep fewer ewes, and keep their shearlings on until the following spring, when they are again shorn and sold to the butchers in the neighbourhood, being too heavy for the London trade. In this case, the lambs are never separated at an early age, but are kept together until 14 months old. In many parts of Leicestershire, the lambs are wintered upon grass only, and are frequently sold fat as early as the following August and September; though some breeders keep them over until the next spring or midsummer. It is the practice with some to draft their ewes at the age of three years or three shears, and place them with a horned Dorset or Southdown ram, for the purpose of feeding what is termed 'lamb and dam.' In this case, the ewes are usually sold in high condition at the Leicester October fair, and are much sought after by different breeders from the adjoining counties. At this fair, a considerable trade is carried on in the sale and letting of rams, it being the conclusion of the season; but the leading breeders prefer 'letting' their sheep at home, which commences on the 8th of June, and continues during the season.

Protection for Sheep.—The affording of protection to sheep, in cold and exposed districts, is one of the oldest and most general of the practices which man has found necessary for the preservation and improvement of his flocks; and

it has varied, in both kind and degree, according to the severity of the climate, the nature of the pastures, the comparative hardiness of the breed, and the comparative enlightenment and resources of the age and country. Six chief kinds of protection are at present available in Britain; and two or more of them, in many situations, are capable of being combined. One is a simple modification of the natural shelter afforded by great or abrupt inequalities in the surface of the pastures; another is the raising of plantations or of stone or turf walls; a third is the constructing of stells, cotes, and other erectional retreats for the flocks; a fourth is the salving or smearing of the bodies of the sheep; a fifth is the covering them with pieces of cloth in the manner technically called bratting; and a sixth is the encouraging of such a variety of fleece as, while of undiminished value for the market, will render the sheep, in a main degree, self-protected. The third of these is noticed sufficiently in the articles Fold and Sheep Stells; the fourth, sufficiently in the articles Salving; and the second, partially in the article Shelter; —so that, in this place, we need only to glance at the second, and to take brief though sufficient notice of the first, the fifth, and the sixth.

Plantation, especially when aided by walls or turf fences, affords excellent protection from storms of wind, rain, and snow; for sheep will always run to it in the time of need, and are always safe while under it. But, in almost all cases, it requires to be produced at the expense of the landlord; for, though a tenant should have a lease of even 19 or 21 years, and should plant at the very commencement of it, in the best way, on the best land, and with the most rapidly growing trees, he could not possibly get shelter enough for his flocks before the expiration of the lease to compensate for his outlay,—and would get no winter shelter whatever for a considerable proportion of the years. The side or quarter of the pastures on which every sheltering plantation should be raised is that where the greatest number and greatest force of storms prevail throughout the year. The trees most suitable, in very exposed situations, are the mountain-ash, the Scotch pine, the beech, the hawthorn, and the oak, with the larch as a temporary nurse. The amount of plantation, on the very bleak uplands, of a somewhat champaign district, or on the moorlands or subordinate ranges of a highland or alpine district, ought not to be less than half an acre at the distance of every mile or every three-fourths of a mile or every half a mile; for if sheep, when overtaken by a storm during the night, do not know of shelter within less than half a mile, they will not leave their lair to obtain it. The best form of plantation, in a glen and extending from the hill to the bottom, is the belt or oblong; but the best in most other situations, particularly on a plateau or on a slowly declining slope, is the square,—and this is greatly aided by a rood of turf wall or of any similar erection running diagonally from each corner.

Modification of natural shelter must vary according to the nature of the ground, and may either be very slight or very considerable according to circumstances. A few sheep farms have such an abundance of dry ravines and abrupt heights, in excellently sheltering directions, as scarcely to need the aid of any planting or building or other similar appliance; and very many or even most possess enough of natural inequality of ground to be easily converted into valuable or sufficient protection by means of pieces of wall and clumps of plantation at the most defective points. Where there is much natural shelter, the first consideration ought to be, whether the ground is dry or wet; and if wet, it ought to be immediately drained; for so long as it is allowed to remain in a wet state, it is altogether unfit for shelter. A judicious store-farmer, by availing himself of the natural inequalities of his ground, and erecting here and there a few roods of turf wall or coarse stone wall, according to the curvature and exposure of the surface, may, in most cases, double the amount of 'beild' at a very trifling expense.

The "bratting" of sheep has been long known, but, till of late years, was rendered a very questionable or a too expensive method of protection, in consequence of the accompaniment of salving, the high price of cloth, and the want of skill in adjusting the brats. The expense of combining salving with bratting was inconveniently great; and the practice of sewing the brat to the wool was at once costly, troublesome, and inefficient, —and very often resulted in the tearing of the fleece, the loosening of the brat, and the tormenting of the animal. But salving—at least in the old and expensive forms of it—can now be greatly modified; cloth is now cheap; and an easy and effective method of adjusting the brat is now practised. "Substances have been discovered," says Mr. MacTurk, in the Transactions of the Highland Society for 1843, "which completely obviate the necessity of smearing, at not more than a half-penny per head, or one-tenth the expense of smearing. Cloth, very well suited for the purpose, may be made from the refuse wool of carpet manufactories, equally thick and warm as a blanket, and this can be got for 6d. per yard. If cloth, such as sacks are made of, be employed, it may be had for 4d. per yard. When intended for bratting hogs, it should be three-quarters wide; and two feet of such cloth will be sufficient for covering one hog. When intended for old sheep of the best description, the brats may be made larger by applying the cloth the long way, and we have then 27 inches of width to cover the back and side instead of 24, and it can be cut off as long as the largest sheep will require. The brat should always come as far down the sides as to cover the widest

part of the ribs, and all the back, from the tail to the back of the neck. The best plan is to select a sheep from the flock, of an average size, and measure the quantity of cloth required for it. When the cloth has been applied to the animal, and its proper dimensions ascertained, the parts should then be marked to which the different straps and strings are to be sewed to hold it in its proper place. A strap must then be fixed to one of the front corners, in a diagonal direction, so as to pass beneath the throat, and sewed to the other corner after it is put on, in the same way as the other straps which are intended to pass through beneath the legs; these must be sewed only at the one end, till the covering be put upon the sheep, and then the other end can be sewed so as to make the brat fit. These straps should be of some soft material, that they may not chafe or injure the skin when the sheep is in motion. If, when made, the brats are dipped in coal tar, it will enable them the better to resist the wet, and prevent them rotting. If taken care of, they will answer the end for five seasons. They ought to be made early in summer, in order that the tar may be dried before the time of using them arrives in November. They ought not to remain on the sheep any longer than the beginning or middle of April, according to the state of the weather and the condition of the flock at the time. We recommend that considerable care should be bestowed in attaching the strings to the proper places in the one first made, so that it may fit well, as it is to serve as a pattern to make the others by. A person who is accustomed to the use of the needle will make one in five minutes, and it may be put on in less than other five. A brat of woollen cloth with the string will not cost more than 5d.; and one of the flaxen ones about 3½d.; but the former will last longer and answer the end better. In order to prevent them being stolen, and to enable the shepherd to distinguish the flock under his charge, they should be all marked with the buisting iron dipped in white paint. Some days before the brats are put on for the winter, the sheep must be poured with some one or other of the bathing mixtures to destroy vermin. Some days after this process, when the wool has regained its usual appearance, the brats should be put on; and the mode in which we recommend this to be done completely obviates the inconveniences arising from the method which has hitherto been practised of sewing it to the wool; for it will be observed that it is wholly attached to the body, and not to the wool, and it therefore possesses this decided advantage over the old method, that it cannot be rubbed off, while, at the same time, it preserves the wool from being so, in case of the pile getting weak from disease or from low condition. When the brat is taken off in April, the wool will be found to have retained the yolk, and will appear quite yellow. When examined, it will be perceived to be sappy and sound, and quite free from the defect that wool staplers call hasky and pinnay, (*i. e.* dry and brittle,) which occasions much loss in the manufacture. When washed, its natural whiteness is quite unimpaired, we would even say increased, from the soap which had been used in pouring, and the yolk which is retained."

The choice and encouragement of a self-protecting fleece is only ancillary to other means of protection in cold and exposed districts, but is of very considerable value in such, and serves as a complete means in low or comparatively warm and genial districts. "Of the varieties of fleece which are preferred," says Mr. MacTurk, "we shall notice first the long, loose, open, lingly fleece which has been gaining ground for the last ten years; and, next, the close fleece, which, 20 years ago, was more generally in request. The only advantage which the former description of fleece possesses over the latter is, that it gives the animal a more showy and bulky appearance, particularly in dry weather, when the piles are tossed about by the wind; but when wet it does not possess even this slight advantage, but, on the contrary, gives the animal a more comfortless appearance than the less showy but more close and serviceable fleece. The same partiality for the long and open fleece prevailed for a time among the breeders of the Leicesters; but the error has been discovered, and now no breeder of any note of that description of stock will lift his voice in defence of it; and there cannot be a doubt that a few years' more experience of it, particularly if the winters are severe, will convince the breeders of black-faced stock of the impropriety of the preference. Indeed we have never met with any store-farmers who will maintain that the open fleece will enable the animal to maintain its condition equally with the close one. The latter, in wet weather, retains the globules of rain upon the top of the fleece, till the animal shakes them off; and it is only in very heavy showers that the fleece allows the rain to penetrate to the skin; but before the open fleece is charged with rain, a shed or opening is formed all the way along the back of the animal, and the rain is thereby allowed at once to find access to the skin, along the surface of which it is conducted; and it cannot then, as in the former case, be shaken off. The same objection applies when there is a fall of snow; but the evil in this case is of a more aggravated character; for the shed in the fleece along the back is often filled with snow for a whole day together. Now is it possible that anything could be more injurious to the health of the animal, or more likely to occasion disease, than that one of the most vital parts of the system, namely, the spine, along which the circulation is conducted, and from which the nerves emanate, should be thus so frequently exposed to the chilling influence of wet and cold for days together? There

is another very serious evil attending the kind of fleece in question, namely, that after the snow has fallen, the ground drift prevails to a very formidable extent; and it is from this kind of drift that the store-farmer has to apprehend most danger to his flock, inasmuch as in nine cases out of ten it is by the rieves of snow thereby accumulated that his flock is overwhelmed; and although the drift may not prevail to a very alarming extent, yet, as the animal seeks food or shelter, or in any way alters his position with regard to the storm, or as the wind swirls from one inequality of the surface of the ground to another, or as the animal encounters a different current of the blast, one part of its loose fleece is lifted after another, and thus every where the snow and wind find access to the skin, till each portion of the fleece is drifted full of snow. It must then, I think, be evident to every one how much these circumstances tend to endanger the life of the animal; and I affirm that a close fleece is better adapted for retaining, in winter, the amount of condition acquired in summer, and the sheep possessing it are thereby a degree in advance in spring. It is contended, on the other hand, that the more open fleece is, in general, longer in the pile, and, therefore that it will yield a greater clip, and that the high prices which have, of late years, been obtained for wool, sufficiently justify the preference which has been given to the sheep which yield it. My experience has led me to an opposite conclusion, and I have almost invariably found that the little additional length which is sometimes found in the more open fleece, is more than counterbalanced by the greater number of piles in the close one, and their superior fineness." SHEEP-COTE. See Fold and Sheep-Stell.

SHEEP-FOLDS. See Fold.

SHEEP-MAGGOT. See Fly-in-Sheep.

SHEEP-PENS. See Hurdle.

SHEEP'S BEARD,—botanically *Arnopogon.* A genus of hardy, ornamental, yellow-flowered, herbaceous, exotic plants, of the succory division of the composite order. Two annual species and a perennial have been introduced to Britain from the South of Europe; and a biennial from the Cape of Good Hope.

SHEEP'S FESCUE. See Festuca.

SHEEP-SHEARING. See Shearing of Sheep.

SHEEP'S-SCABIOUS,—botanically *Jasione.* A small genus of ornamental herbaceous plants, of the bellflower order. The mountain sheep's-scabious, or common sheep's-bit, *Jasione montana,* abounds on the sandy pastures and dry heathy grounds of Britain. Its root is annual; its herbage is rough with short rigid hairs; its stems are either simple or branched and from 4 to 15 inches high; its leaves are sessile; and its flowers grow in a terminal tuft or head, and have a fine blue colour, and bloom in June and July. Two perennial-rooted, evergreen, blue-flowered species,—the dwarf and the perennial, the former about 6 inches high and blooming from June till September, and the latter about a foot high and blooming in June and July,—have been introduced to Britain from France, and are well adapted for ornamental rockwork.

SHEEP'S-SORREL. See Sorrel.

SHEEP-STELL. A place of retreat and security for sheep during the prevalence of a mountain-storm. It differs from every kind of fold in being, not simply a place for feeding, but principally an asylum from danger. Stells are exceedingly various in size, form, material, position, and appliance; and they must, in a general view, have just the construction and character which will best suit the exigencies of each particular farm. But a very common and very good one is simply a circular wall, about 30 feet in diameter, about 6½ feet in height, on dry ground, on as level a spot as possible, in such a situation that the drifting snow may be expected to be carried clear of the pasture, and accompanied, on one side, with a hay-yard of about 21 feet by 15; and such a stell is specially efficient when a large enough plantation extends on the weather side of it to break the force of the prevailing winds, and when a wall of two roods in length is attached on the side opposite the hay-yard. A set of structures like this will well serve for eight scores of sheep; and should stand on a part of the farm to which the flock naturally resort in winter. When flocks are large, a comparatively large number of stells at comparatively small distances, all about the size which we have indicated, are very greatly preferable to a lesser number at wider distances. No hollow should intervene between any stell and the adjacent hill or acclivity; for a hollow in such a position is liable to be filled with drifted snow at the very outset of a storm, and may in consequence arrest the retreat of the flock from the hill to the shelter. A circular form of stell is preferable to any other form for winter protec-

tion, on account of its seldom affording permanent or injurious lodgment to snow; for, when any considerable degree of wind prevails, no sooner does the snow come within the wall, than it is elevated by the whirling blast or current which sweeps the enclosure, and is carried over the wall and thrown out; and even when no wind blows, and when the snow lies and accumulates steadily where it falls, the sheep within the stell always keep above it, and have been known, in a case of heavy and long-continued fall, even to raise themselves upon the accumulating deposit to the very level of the wall. Some persons, however, prefer winter-stells in the form of the letter T, or in that of the letter H, or in that of the letter S, or in that of various lines and curvatures expressly adapted to the special configuration of the ground; and others have attempted, with more or less success, to combine the properties of winter-stell and summer-stell by means of a complex form of projecting enclosures and intermediate recesses,—the former for retreat from snow-storms, and the latter for shelter from hurricanes. But summer-stells are wanted in different situations from the winter ones, and do best within or near the brow of hills, in spots to which the flocks most frequently retreat from the fury of the blast, and may consist only of a semicircle or two transverse walls on a declivity, or of three walls diverging from a common centre on the top of a knoll, or of a single line of wall on the wing of a cliff or precipitous escarpment. See the articles Fold and Shelter.

SHEEP-WALK. See Pasture.

SHELL. A hard, close, cubical envelope, either natural or artificial. The word is used in very many and widely different senses; but it concerns a naturalist or an agriculturist principally in the sense of the hard, calcareous coat of birds' eggs and of the bodies of molluscs and crustaceans. A shell, in this sense, is a mineral substance, with some intermixture of animal matter; and, when properly used, acts readily and richly as a fertilizer of the soil. Egg shells consist principally of carbonate of lime with some magnesia, but comprise about one per cent. of phosphate of lime and magnesia, and from two to four per cent. of animal matter; the shells of molluscs have a compact texture, an enamelled surface, and sometimes splendid variegation of tint and outline, and consist almost entirely of carbonate of lime, with layers of coagulated albumen, or with a soft animal substance similar to gelatine; and the shells of crustaceans contain a large proportion of carbonate of lime, a considerable proportion of phosphate of lime, and a quantity of cartilaginous matter similar to coagulated albumen. The comminuted shells deposited by the tides or embedded in the bottom of bays and estuaries, form both an abundant and an excellent manure. See the articles Sand and Shell-Sand. Large quantities of entire or partially broken shells, whether obtained from natural deposits or accumulated artificially, may be prepared for prompt manurial action either by pulverization or by calcination; but though, in the latter way, they fall readily to powder, they are liable to sustain a wasteful loss of their animal matter. See the articles Oyster and Animal Manures.

SHELL-LAC. See Lac and Coccus.

SHELL-SAND. A natural mixture of sea-sand and comminuted shells. See the article Sand. "The shell-sand of our coasts is often obtained in the state of a fine powder; and in that form it acts better than in a coarser form, and the same weight goes farther. But none of it is so fine as the powder to which slaked lime falls. It has, therefore, occurred to many that it might be rendered more valuable by a partial burning. The shell-sand which is collected on our coasts contains a variable proportion of sea-sand. This sometimes is as little as 5 or 10, but at other times it amounts to as much as 50 or 60 per cent. of its whole weight. This variation will, of course, affect its value as a manure in whatever state it is applied. In consequence of this admixture of sand among the shells, it will unavoidably happen, during the burning of them, that in those parts of the fire or kiln where the heat is greatest, a portion of the sand and lime will occasionally melt together, and form a silicate of lime. So much of the lime as has thus been converted into silicate, will, of course, be less immediate in its action upon the soil, although it will be by no means without an ultimate good effect. When mixed with the soil, it will by degrees be reconverted into carbonate, and will at the same time liberate a portion of silica in that soluble state in which, in some soils, it may possibly promote the growth of the corn crop and strengthen the straw. This roasting or burning of the shell-sand has been tried with success in Cornwall. By burning it has been found to become so brittle as easily to be reduced to a fine powder; and in this powdery state, it has produced on several farms, a marked increase in the crops of roots and corn. This was of course to be expected, especially on cold undrained lands, and such as were naturally poor in lime. The native shell-sand would have produced the same effects in a less marked degree. Ordinary lime shells, newly fallen or slacked, would have produced a fully equal effect. This method of burning the shell-sand, therefore, though it greatly inproves it, does not give it virtues which other lime does not possess." [Report of the Agricultural Chemistry Association of Scotland.]

SHELTER. The sheltering of sheep is treated in the articles Sheep, Sheep-Stell, and Fold; the sheltering of cattle is noticed in the article Feeding of Animals; and the sheltering of fields and pastures and tracts of country is disposed of in the articles Plantation, Enclosure, Fence, Wall, and Hedge. In this place, therefore, we

shall merely point out, in a general way, the effects of shelter, with the view of inducing all classes of landowners and land-cultivators to appreciate and promote it; and this we cannot better do than in abstracts from a series of able papers on the subject, by Mr. Donald Bain of Edinburgh, in the Quarterly Journal of Agriculture.

"Of all things," says Mr. Bain, "shelter would seem a subject that need only be mentioned to recommend itself in a country such as this. In regard to the natural body, we admit at once the value of this system. In regard to that body, indeed, three things in particular are required, — dryness, warmth, and sufficient food. Of these three things, the last, or food, is, of course, indispensable to existence; but are not dryness and warmth nearly equally so? Nay, with dryness and warmth, the individual may live and enjoy comfort with even insufficient food; but no extent of food could preserve him in health, or even from death, without dryness and warmth. It is so with the earth, and with all the fruits of the earth, and all that live upon it and them. In countries naturally cold, all animals destined to live in them are endowed with suitable coverings, excepting man; and he borrows from the earth and from other animals, and in the coldest country surrounds himself with the temperature necessary to his comfort, or he does not prosper. He has only to consider this condition of his own existence, to see at once what he ought to do for any plants or animals he may find it profitable to rear; unless, indeed, we should rather import a climate from other countries, as well as corn and cattle. In particular instances, we already pay attention to shelter, in regard to the plants of the garden and hothouse, and the animals of the menagerie; but as a general principle, and in regard to those plants and those animals it is most important we should care for, we are most recklessly and unphilosophically negligent. Yet this is like being wise in trivial matters and neglecting the weighty points of the law; we care where we are compelled to care,—where without care the plant or the animal would die; but to all short of this we are indifferent, though policy and humanity alike dictate conduct entirely opposite. If fields of corn or flocks of sheep only occasionally perish from want of shelter, though, as a general matter, they *all but* perish, we are contented; we put up with the loss as an effect of climate instead of an effect of negligence; we endure the loss instead of preventing it, and suffer it to be deducted from income when we might add it to it. We do this from habit and heedlessness; yet it is not one bit wiser than it is in the savages of western America to construct themselves mounds on the banks of rivers to which to run when the floods come, and die from famine, so far as they escape the waters, instead of embanking the rivers, as the inhabitants of Holland have done even by the sea. Year after year the savages perish, of course, in thousands, and have their health destroyed to the extent of many thousands more by flood and famine, and the pestilence consequence on both; yet they are untaught, and being now nearly confined to those regions, they will speedily die out, and consider it a natural necessity of their situation; whereas we see that there is no natural necessity in the case, but that they are merely unteachable. And, year after year, we have crops wasted and cattle starved from want of shelter, and flocks of sheep buried in snow or carried away by every paltry burn, because there are no proper residences for shepherds to attend them, and no food or shelter to which to drive them on the coming on of floods or storms. To all this we submit, and deduct for such probable casualties from the rents agreed to be paid, instead of removing the casualties; and landlords know and suffer this, though there would be nothing easier than to prevent it. Is not this admirable management? Passing over the inhumanity to the people employed, and the animals thus called into existence to be destroyed or starved, is it not barbarous in an economical point of view? What should we think of a general who should thus suffer his army to be decimated, when by proper care he might prevent it?—of a farmer even, who, by neglecting the precautions he has agreed to consider necessary, should allow his crops to be wasted by frost, or his horses by want of stabling? Yet the want of any degree of shelter to crop or stock, that in its results would overpay the cost, is just as barbarous as any of the cases I have supposed.

"There is little doubt that, from imperfect shelter, there is not only a direct general loss from death or non-production, but also a waste of food to cattle and of manure for the fields, to an amount scarcely to be calculated. We may easily be satisfied of this by general reasoning, without the test of experiments; for what is the use of shelter? and what are its effects? Its use, as vegetable life is concerned, is very various. We are all now aware that vegetation derives its principal nourishment, not from the earth, but from the air,—from the dews that are constantly falling from the heavens, and the gases that are ever evolving in or rising from the earth, assisted, of course, by the proper temperature produced by the sun and earth. Well, how can a blade of corn, or of any crop, imbibe the necessary nourishment from dew or air, or enjoy a healthful existence, or even live, if perpetually scourged by petrifying winds? Can we expect anything to prosper in such circumstances,—having neither food, nor warmth, nor rest? We cannot. We see, in consequence, whole fields of the most promising crops, in one night or day, scourged into dry and withered blades, or smitten to blackness from unbearable cold. These crops may recover if the malignant influence shall not

be continued too long, as a man or animal may recover from incipient consumption; but is not the constitution of both tried and their existence perilled? and if these trials and risks might have been prevented, ought they not to have been so?—Again, why is the grass always greenest or the crop most luxuriant by the side of a shelter? It is not because most manure has been applied there, for very probably no manure whatever has been applied there. But suppose equal manure to have been applied, still the question remains, Why is the crop there both strongest and greenest? It is because there you will see the dew resting, like silver, on every spike, affording its nourishment undisturbed, like a mother nursing her infant in some nook sheltered from the wind, and only exposed to the sun, and soft and gentle air. To such a corner the hardiest animal is happy to repair, to feed or ruminate, even in the kindliest season; how much more when the cold and blighting wind is raging and the tempest of rain or snow? And these cold winds rage with us much too often, especially in spring, when both plants and animals require most to be sheltered from them. But if in spring shelter is necessary, it is not less expedient in every season, as not only averting disease from plants and animals, but effecting a vast saving of food and energy to both. I have lately read, in a most respectable English Journal, the result apparently of some experiments on the very subject on which I have been reasoning. They are headed, 'Effects of Cold and Heat in Fattening,' and are abridged as follows:—'It is well known that cattle do not fatten so well in cold weather as in hot. The reason is this. The fat is a highly carbonized substance, formed by animals from their carbonaceous food. In cold weather, the carbon in this food is consumed in keeping up the heat of the animal, which is at that season more rapidly carried off. This is also illustrated in an experiment made by Lord Ducie at Whitfield. One hundred sheep were placed in a shed, and ate 21 lbs. of swedes, each, per day, another hundred were placed in the open air, and ate 25 lbs. of swedes per day, yet, at the end of a certain period, the sheep which were protected, although they had a fifth less food, weighed 3 lbs. a-head more than the unprotected sheep. The reason of this,' it is continued, 'is obvious: the exposed sheep had their carbonaceous food consumed in keeping up their animal heat,'—that is, as he has mentioned, from being carried off by the air; as it is long since it has been established, that a man would lose more weight from being exposed without covering, by exsiccation, than he would in the same time by perspiration, though in the warmest dress. 'Warmth,' continues the reporter, 'is thus seen to be an equivalent for food,'—meaning, in this case, to animals, but I say also to plants; and to both the result is from saving of waste. 'This is also established by the fact that two hives of bees do not consume so much honey when together as when separate, on account of the warmth being greater. Cattle, from the same reason, thrive much better when kept warm than when exposed to cold.'

"We have, therefore, thus established, at one and the same time, at once the direct advantage and the economy of warmth; for warmth is not only productive of health and strength to the animal, but these at a greatly reduced expense of food. Hold the advantage or saving to be only 20 per cent.,—and, from the experiment quoted, it is shown to be greatly more; and what an immense sum would this be, spread over the flocks and herds maintained by pasture in these kingdoms? There is another view,—the loss of sheep, and lambs in particular, from casualties, including want of warmth; and, from a distinct record of this description now before me, kept by an intelligent shepherd for 17 years, the mean annual loss of old sheep or hoggs is 20¾ per cent., or upwards of one-fifth! and this without reckoning the loss of lambs, estimated also at 20 per cent.; or converting the lambs into sheep, raising the per centage in general to 27 per cent. And this last estimate has reference to a southland farm. What the losses are on the unapproachable hills, and in the chasms and gullies of the west and north, has never, perhaps, been attempted to be shown; but, in their present neglected condition, it may be conceived.—And as gainful as warmth is in the case of animals, it is certainly also in the case of plants,—perhaps more so. For though in plants also we find the strong stem can with more probability recover the effects of a blight, it, at the same time, suffers by it with more intensity, and requires, consequently, a corresponding waste of food and energy to recover it, that is, of manure and of sun; which last, though costing no direct expense, is the last thing that should be wasted in this climate, because, in this climate, such waste is ruinous.—And what so contributes to warmth as shelter? What so completely economizes the heat both of the earth and of the sun? And how does it economize both, and the dews and gases they evolve between them? By preserving them from being swept away, and by allowing them to be generated in the greatest quantity and of the highest temperature. If we will only walk in the street of a city exposed to the sun, we shall have a perfect example of how the heat is economized and the temperature increased. From reverberation it becomes at last painful, if combined with a moderate degree of calm. In the neighbourhood of a wood facing the sun, or in an enclosure formed by shelters of moderate height, the illustration is both more pleasing and more complete. There the heat is less reverberated. It is absorbed by the earth, and rendered at once more genial and less oppressive. But a moderate degree of heat, thus economized, is indeed of the utmost utility. The

air that, between the gases evolved from the earth and the dews that had been deposited from the clouds, may be termed medicated to the plants that require its nourishment, is not wasted, is not swept away, or dried up; neither is it scorched or rendered stagnant; but, by moderate shelter, is rendered duly warm, and applied in quiet; and the plant and the animal alike enjoy the genial influence. In short, by shelter we create a climate; and is it necessary to say anything more?

"There is hardly a spot in Scotland, nor, of course, in England, or Ireland, that might not be rendered of a kindly temperament by shelter. It is not absolute height that renders our plains and mountains cold,—it is merely relative height; that, being the highest, and unsheltered by anything higher, the air passes over them unchecked and unmitigated, and, acquiring strength as it goes, becomes at last scourging and destructive. Upon a surface so swept, the sun can take no effect, nor can the earth impart any warmth; the influence of both is overborne by cold and scourging winds. But where the gale is checked, and the air over any particular spot is rendered tranquil, it soon becomes warm, either from the direct heat of the sun or the latent warmth of the earth. The enclosed space, though on the highest hill, becomes in effect a valley, for it is surrounded by higher objects. Its air becomes attempered, its climate and consequently its soil improved; for it becomes the seat of vegetation, and draws nourishment from the previously idle and scourging air; and the blast that was previously destructive, and, like a marauding army, overrun the space, leaving desolation only behind it, is now arrested, and made to yield, to the very woods that arrest it, the nourishment they need, —is turned from an enemy, levelling all before it, into a subservient drudge, to yield food and water to the hills, as well as to the plains, and enrich where it had previously impoverished. Need I say to intelligent readers that this is no fancy picture? No, for every object around them, and every reflection upon it, will convince them of its truth. The lowest plain, if swept by a scourging wind, is barren, or next to barren, whatever may be its soil; and on the other hand, on the highest hills, if we find a valley, it is fertile, precisely because it is not swept by cold and scourging winds."

"Let any one look at a moor where plantations have been raised, and he will find as follows:—First, if the wood has been properly planted, and fenced, and thinned, that is, if proper care has been taken to make the plant reach the subsoil, to shelter it while growing, and in due time to provide room for its growth, the wood is thriving; and instead of heath, as was the original covering of the soil, it is now covered between the trees by a rich, and if they are close, an exceedingly silky grass. Even the heath at the outskirts, if any remains, has a softer and more luxuriant character than the stunted article of the same description without the enclosure. It may be said this is produced by the manure annually furnished by the falling leaves,—and this *may* promote the richness and luxuriance of the grass; but the efficacy of shelter is evident from this, that the grass is often finest and richest where there is shelter only, and no manure from the falling leaves, that is, in casual openings of the plantation. Next, if corn-fields have been created under shelter of the woods, they will generally be found luxuriant, while beyond this, there is first coldness, and a light crop,—and beyond this perhaps heath; or even one side of the wood is thin and stunted, and the other, which has been sheltered by this stunted part, is thriving and vigorous. A more remarkable evidence of the benefits of shelter, and of the consequences of the want of it, may be stated as follows:—where a dyke has been raised of a certain height, and trees planted within it, the trees are cut by the blast as if by a hedge-knife, exactly in the direction the blast has received from the coping of the wall; that is, if the wall is flat at the top, the wood has suffered far in; if the angle of the top is small, the cut of the trees is exactly of the same angle, and extends far in, in proportion to the flatness of the angle; but if the angle is very acute, and sends the blast almost directly upwards, the wood almost escapes,—the tree by the wall is slightly cut, and no more. These facts may not have been noticed in any scientific publication, but they are open to every observer; and they suggest many ideas of the utmost importance, as regards this division of the empire. They suggest, first, the great utility of shelter as a general principle; next, that where woods are planted, the wall opposed to the most prevalent or most destructive wind, should be of considerable height; and third, that even the form of the coping of dykes for woods or fields, is of consequence, and that it should always be of such an angle, as to send the blast (which in all cases will obey it more or less), almost directly upwards.

"By proper shelter, almost every part of this kingdom might be brought into a state of warmth and productiveness. Ranges of moor, apparently the most barren, might be rendered warm and kindly to every species of vegetation. Even hills, were it worth while to contend with them, might be conquered by successive belts of wood; and if not cultivated (as they evidently have in many instances been), at least made of double or triple value for pasture. But our common moors and moorland require nothing so much as shelter; and even where the lands are not moorish, but much exposed, shelter is necessary both to the fields and flocks, and nothing can so much enhance their value. And it is not continued ring-fences, clapped down any where, or any how, that should be recommended in this

matter. When an engineer wishes to oppose the tide, he does not put down a long dead wall; he puts down in the strength of the current, a point of great power, and as the strength of the current, thus broken, diminishes, he diminishes his defences, and finally leaves the matter to the tide itself, when fully broken, to the desired direction. In like manner, the person dealing with the winds, should consider where they bear hardest, and where they may be made to trend away with advantage, and suit his defences to the exigency, whether in height or strength. A very slight defence, for example, placed on a height exposed to the east, may not only protect that height, but shelter a long reach of lower land. The whole east coast of Scotland is bold, and it is bare. A belt of wood behind a wall of proper height, and presenting proper angles to the blast, might shelter whole districts inland; and so, of any other exposure, art is in this case, as in most others, greatly more than strength. An hundred yards of wall or of wood, rightly placed, may do more than a thousand placed without skill. Put down without judgment, indeed, intended defences may do manifest injury, for they may shut out the most kindly influences, and expose the crop to a cataract of included winds. But, as a general position, shelter is, in Scotland, of the greatest value; it is nearly a national object; it might reclaim many thousand acres that without it never can be reclaimed, and almost incalculably improve many thousands more. In a recent history of Devonshire, it is said, 'In this part of the country, the fences are chiefly high mounds, surmounted by coppice-woods, which not only afford a sufficient supply of fuel, but also a surplus of poles, cordwood, faggots, and oak-bark for sale. This kind of product is considered a crop of some value, in addition to its utility as a fence; as it affords to the pasturing animals excellent protection from wind and sun, with but moderate care and expense in repairing. These hedges are better adapted to the hilly surface of Devon, than to more level countries, commonly forming altogether a barrier thirty feet high, which so softens the rigour of the unfriendly blasts, that many of the inferior hills are cultivated to the very summits. A stranger unaware of the practice, considers himself as travelling in deep hollow ways, for miles, till arriving at some elevated opening, he is charmed with the delightful scenery of the fertile country he has passed.' This places the principle of shelter on a large scale, so completely on the footing of an approved practice, in one of the counties of England, apparently made 'the finest' by this very practice, that there seems to be no necessity for giving the idea out with fear. The whole of the east coast of Scotland should be sheltered by high mounds, either carrying or protecting wood; and in every situation where the plains or valleys are swept by scourging blasts, similar impediments should be put down. This acted upon as a general principle, for a few years, would entirely change the climate and aspect and even the soil of many parts of Scotland; for as money makes money, so heavy crops lead to heavier crops, by enriching at once the soil and the cultivator, from making more manure, and sheltering and fining the soil. There is no part of Scotland, or England, or Ireland, that may not be sheltered at less expense than the wilds of America may be cleared, and with more certainty of a market for the proceeds. Sheltering leases, therefore, should be granted, as improving leases have been; and speedily we should see shelters rise, as profitable to the raisers, as pleasing and profitable to the country."

SHEPHERD. A person who has the care and management of a flock of sheep. A shepherd in eastern countries and in patriarchal times is a character of intense interest, and forms the subject of many of the most glorious and sublime allusions in the best of books. See the article SHEEP. Even a hill-shepherd, in our own country, at the present day, is, or ought to be, one of the choicest of rural men,—eminent for common sense and country skill, in all matters of ordinary observation, distinguished for wisdom and kindness in the discharge of his immediate duties, and lifted high into the purest philosophy and the most religious devotion by the peculiar influences of his position. Hogg, the well-known Ettrick Shepherd, was a remarkable instance of how the tending of flocks may warm the heart and fire the genius and light up the whole intellect into a luminary; and, in spite of all the doubtfulness and darkness of his higher speculations, even he spake of the mountain shepherd "seeing God in the clouds," and being almost of necessity an intensely religious man. "The daily feeling naturally impressed on the shepherd's mind," said he, "that all his comforts are so entirely in the hand of Him that rules the elements, contributes not a little to that firm spirit of devotion for which the Scottish shepherd is so distinguished. I know of no scene so impressive as that of a family sequestered in a low glen during the time of a winter storm; and where is the glen in the kingdom that wants such a habitation? There they are left to the protection of heaven, and they know and feel it. Throughout all the wild vicissitudes of nature, they have no hope of any assistance from man, but are conversant with the Almighty alone. Before retiring to rest, the shepherd uniformly goes out to examine the state of the weather, and makes his report to the little dependent group within; nothing is to be seen but the conflict of the elements, nor heard but the roaring of the storm; then they all kneel around him while he recommends them to the protection of heaven; and though their little hymns of praise can scarcely be heard, even by themselves, as they mix with the roar of the tempest, they

never fail to rise from their devotions with their spirits cheered and their confidence renewed, and go to sleep with an exaltation of mind of which kings and conquerors have no share. Often have I been a sharer in such scenes, and never even in my youngest years without having my heart daily impressed by the circumstances. There is a sublimity in the very idea. There we lived, as it were, inmates of the cloud and of the storm; but we stood in a relationship to the Ruler of these that neither time nor eternity could efface."

A shepherd requires no small amount of perspicacity and kindness and general excellence for the discharge of even his proper duties. "Much of the success in sheep-farming," remarks Mr. Little, in his Practical Observations on Mountain Sheep, "depends on the skill and application of the shepherd. As his situation is one of considerable trust, he ought to be honest, active, useful, and of a calm temper; for if at any time a shepherd gets into a passion with his sheep, it is attended with great disadvantage in herding, or in working among them. The qualification required in taking care of a hirsel, (or flock,) is not in running, hounding, and training dogs, or in performing a day's work of any other kind; but to direct them according to the soil, climate, and situation of the farm, in such a manner as to obtain the greatest quantity of food at all seasons of the year. Their health and comfort should be carefully looked after by the shepherd; and if his exertions are made with judgment, they are of very great consequence to the farmer. It is not by walking much, and doing a great deal, that a shepherd is a good one, but it is knowing where to walk so as to disturb the sheep the least, and by doing at the time whatever is necessary to be done. There is not an experienced shepherd who has been any length of time on one farm, who does not, as soon as he rises in the morning, and observes the state of the weather, know almost to a certainty where to find every sheep on the hill, and will accordingly take his course to the places he knows his presence is most wanted. The object in looking over a hill every evening and morning, is to ascertain if there be no trespassers nor diseases among the sheep which require looking after. If any of your own or neighbour's sheep have trespassed, it is very foolish to dog or abuse them; for the more gently you can turn them back the better. If the boundary should be on the top of a height, to which sheep are apt to draw at night, it is better to turn your own a little closer to the boundary in the afternoon, than to turn back your neighbour's,—and it will answer the same purpose; and if the two flocks are gently divided in the morning, without dogs, they will become so well acquainted with their own side, that at the very sight of the shepherd, they will take to it without farther trouble. Those shepherds who dog, force, and shed much about a march, I consider them as bad herds for their masters as for the neighbouring farmer. When a sheep dies on the hill, or any disease appears among them, the dead or diseased sheep should be removed immediately, but particularly so if the disease appears of an infectious nature. Looking regularly over a hill is of great consequence, also, in case of any sheep falling into a ditch, or a lamb losing its mother, or when they are annoyed by flies or maggots, or by foxes or dogs worrying them, or when they fall on their backs and cannot get up again. Knowing sheep by headmark often saves a shepherd much trouble, particularly in the lambing season, and at all sortings of the sheep; yet there are many good shepherds who do not know sheep by headmark, and there are some very ordinary ones who have a talent in that way. Every individual may be known by the stock-mark. To possess the knack of counting sheep readily is of no small service to a shepherd; for he ought always to be able to count his flock when he makes his rounds on the hill. There are few shepherds who accustom themselves to count sheep, who cannot, whenever they meet with them on a hill, count 100 going at large, or even 200; and it seldom happens that a greater number than 200 will be found together in an open hirsel. To know the number in the different lots is of great use in case of a hasty blast, as you can, in that event, know almost to a certainty, whether or not any sheep are awanting, and from what part of the farm. A shepherd ought likewise to be able to do any kind of work about a sheep-farm, such as cutting lambs, smearing, slaughtering, dressing for the market, repairing stone-dykes, cleaning out drains, mowing grass, making hay, casting and winning peat-turf for fuel, &c.; but he ought at no time to neglect the sheep for such work."

SHEPHERDIA. A small genus of hardy, ornamental, North American shrubs, of the oleaster family.—The Canadian species, *Shepherdia canadensis*—called by the old botanists *Hippophae canadensis*—was introduced to Britain in 1759. It closely resembles the common sea-buckthorn in general appearance, and attains about the same height, and has nearly the same dark brown colour of bark on its branches, and blooms at the same period, but may readily be distinguished by its oval-shaped leaves. It thrives in any common soil, and may be propagated from suckers, layers, or cuttings.—The silvery species, *Shepherdia argentea*, abounds on the banks of the Missouri, and was introduced to Britain in 1818. It commonly attains a height of from 10 to 14 feet; and is highly esteemed for the silvery splendour of its foliage; and may be readily propagated from layers; but is of slow growth, and sometimes of a very dwarfish habit. Its leaves are petiolate, entire, oblong-ovate, obtuse, smooth, and covered with peltate silvery scales; its flowers, as also those of the preceding species, are

dicœcious, and apetalous, and bloom in April and May; and its fruit are diaphanous, scarlet berries, with a pleasantly acid taste. This species loves a soil of peaty loam.

SHEPHERD'S CLUB. See Mullein.

SHEPHERD'S CROOK. A cylindrical iron rod, peculiarly bent into a narrow hook-like form, and mounted upon a long wooden shaft. It is used for catching sheep, and serves the purpose well in dexterous hands; but requires to be employed with great caution by a novice.

SHEPHERD'S DOG. See Dog.

SHEPHERD'S NEEDLE. See Scandix.

SHEPHERD'S PURSE,—botanically *Capsella* and *Thlaspi*. Two genera of herbaceous plants, of the cruciferous order.—The common shepherd's purse, *Capsella bursa-pastoris*—called by Linnæus *Thlaspi bursa-pastoris*—is an annual weed of road sides and similar situations in Britain and in most other countries of the world. Its root is tapering and whitish and has a smoke-like odour; its herbage is rough with hairs; its stem is branched, leafy, and from 6 to 20 inches high; its radical leaves are deeply pinnatifid; its flowers are corymbose, small, white, and often tinged with purplish brown, and bloom from February till November; and its capsules are inversely heart-shaped and somewhat triangular, and contain about 5 seeds or upwards in each cell. The flowers and seeds are eaten by birds. Four very distinct varieties, besides the normal plant, occur wild in Britain,—the smaller, the apetalous, the entire-leaved, and the buckthorn-leaved.—The corn shepherd's purse or penny cress, *Thlaspi arvense*, is an annual weed of the corn fields of Britain. Its stem is 6 or 8 inches high, and its flowers are white, and bloom in June and July.—The alpine shepherd's purse, *Thlaspi alpestre*, is a perennial-rooted weed of the meadows and pastures of some parts of England. It has a height of about 6 inches, and carries white flowers from May till July.—The perfoliate shepherd's purse, *Thlaspi perfoliatum*, is a biennial weed of the stony grounds of some parts of England. It is also about 6 inches high and white flowered, and blooms from April till July. —Five or six exotic species of Thlaspi have been introduced to the botanical collections of Britain; and 8 or 9 more are known.

SHERARDIA. See Field-Madder.

SHERDS. Fragments of earthen pots, used in gardening for under-draining gravel walks, and for forming a drainage stratum beneath the soil of potted plants.

SHIELD-FERN. See Aspidium.

SHIFT. See Rotation.

SHIM. See Plough.

SHINGLES. Pieces of thin board, used for covering roofs in the manner of tiles and slates.

SHOCK, or Stook. A small stack of sheaves of corn, set up in the field as soon as the corn is cut and the sheaves are bound, in order that they may dry. Eight or more sheaves are set on end in pairs leaning against each other; and two or four, called hoods or heading sheaves, are laid horizontally over them, by way of roof or covering to protect them from the weather. The size and form and constructing of shocks vary in different districts. Never more than ten sheaves are allowed to a shock in many parts of England; but so many as twelve or fourteen are common in the best parts of Scotland. The constructing of shocks is generally neater and more efficient in Scotland than in England.

SHOEING. The artificial surface upon which the horse is made to tread in the performance of his labour—roads and pavements of various descriptions—requires that his feet should be furnished with some artificial defence; otherwise, his hoofs would speedily wear away, exposing the quick or sensitive parts of the foot, and rendering him so lame as to be perfectly useless. In some countries—in the sandy deserts of Arabia, for example—no such defence is said to be requisite, at least for ordinary purposes; indeed, even in our own country, we may ride some horses for weeks and months together, with only sufficient shoe to cover the toe of the hoof, the part most subjected to friction and fracture.

Whatever kind of shoe is used should consist of such material and be made of such a form as to interfere in the least possible degree with the internal mechanism and functions of the foot, at the same time that it serves every purpose of defending the hoof. A shoe made of any elastic or yielding material, possesses many advantages over one of an opposite description, because it allows of the expansion and contraction of the hoof; but every such shoe is found by experience not to be adequately substantial and durable. A leathern shoe would hardly last for a single journey; and even if it were durable, it would want resistance sufficient to guard against fracture of the hoof. Iron, therefore, has almost universally become the material employed; and although manifold alterations and some improvements have taken place in the form and construction of the shoes, iron, in some way or other, is still the substance of which all are made.

The toughness of the hoof and the strength of the crust afford a ready means of attaching the shoe; but as this must be effected by means of nails, and as these must be continued round a considerable part of the hoof, the crust becomes firmly fixed to the shoe, so as almost entirely to prevent the natural and necessary expansion and contraction of that part of the hoof; and as the action of the whole depends in a considerable degree upon the individual parts, a general derangement of the whole foot is a necessary consequence of the interruption of these functions. It must have appeared, on the first application of a shoe, that it was necessary to allow a degree of freedom to the motion of the horny sole, because constant firm pressure on it, even in the strongest feet, will produce lameness; con-

sequently the earliest and the most rudely constructed horse-shoe that we find for the fore feet, was formed so as to admit in a certain degree of the motion or descent of the sole. But it was afterwards found, as more particular attention came to be paid to the diseases of the feet, that many of the rarer or more deep-seated of these arose from the means adopted to prevent the more obvious. The simplest and readiest method of preventing pressure upon the sole, by allowing its descent, was to bevel off the shoe in such a manner that the crust of the hoof could only rest on the outer edge of it; thus leaving a sufficient space for the descent of the sole. Such a construction, however, involved the foot in more serious consequences. The sides and extremities of the crust, resting upon an inclined plane, when the animal is made to perform the ordinary exertions to which he is commonly applied, are made to approximate each other at every step; and, instead of the liberty of action, and the expansion of hoof which would take place in the natural and unrestrained state, the foot becomes so squeezed as to occasion great pain to the animal, and to involve a total destruction of its own functions. Connected with shoeing, arises another inconvenience, in the gradual growth of the hoof, which, exposed in a state of nature, is constantly being worn away, but, by the protection of the shoe, becomes abundant, and requires to be cut down more or less at different periods. The paring of the hoof being of necessity entrusted to those who apply the shoe, and they viewing the operation as an indifferent matter, a careless and improper removal of the hoof is almost a certain consequence, by which means parts that ought to be left strong and well protected are removed, while those which ought to be removed are commonly allowed to remain; and, in consequence, the feet become distorted, and disease is rapidly induced.

Amongst the first who attempted to remedy these defects was La Fosse, who considered the principal evils to arise from the construction of the common shoe raising the heels and frog from the ground, so as to deprive the tendons, when in action, of the necessary support which they receive from the frog in a state of nature resting upon the ground; and to obviate these mischiefs, he strongly recommended the short thin-heeled or half-moon shoe, extending round the toe, and back to the quarters, and to leave the sole and frog unpared. The heels and quarters being thus left at liberty, and the frog brought in contact with the ground, the foot somewhat approaches the natural state. But, while this shoe may be applied with safety and advantage to strong feet, the varieties that occur, both in the form and strength of different feet, and in the construction of the limbs of many horses, set narrow limits to the advantages that were at first expected to arise from its adoption. The tendons of the limb, instead of being relieved by it, seemed to suffer more frequently than before, because the elongation of the toe by the gradual growth of horn, and the addition of the shoe upon frequently an improperly prepared foot, threw a greater instead of a less strain upon the tendons, more especially in long pasterned horses, and thus a formidable objection to it was raised, which, together with its obvious inapplicability to very low weak-heeled feet, prevented it from passing into permanent repute.

Osmer, J. Clark, and Moorcroft, considering that the evils produced by shoeing arose chiefly from the bevelling of the shoe, improper paring, and unequal pressure, introduced and recommended the seated concave shoe, now most commonly in use in the most respectable forges in this country; and the fact that it has continued to be generally approved, notwithstanding many more modern attempts to substitute something better, is almost enough to establish its superiority over at least the majority of other forms of horse-shoes. A properly made seated shoe is formed nearly of an equal thickness on its outer edge, from the heel to the toe. On the surface next the hoof, a portion is left quite flat for the crust to rest upon, which flat part is continued all round the outer edge of the hoof surface, but is, at each heel, the full breadth of the shoe for the junction of the crust and bars to rest upon. By this means, the hoof which rests upon it is not squeezed or inclined in, as in the old plan of shoeing; nay, at the extremities of the heels, it may be so arranged, that, instead of inclining the crust inwards, it may be bevelled off, so as to form an inclined plane outwards, and thus assist in expanding the foot. After sufficient space is left for the resting of the crust, the remainder of the web (the inner part of the shoe) is bevelled off, so as to leave a space, when the shoe is put upon the foot, sufficient to allow a picker to pass freely all around between it and the horny sole. By this arrangement, the shoe is tightened, and a flat or even a concave surface may be exposed to the ground, by which the animal's step is rendered secure. To preserve the shoe safely in its situation, it is pierced with either seven or eight nail holes for a moderate sized horse, and with a greater number for larger ones. These holes are generally pierced from a groove, technically termed the fullering, made in the ground surface; and though they may be stamped at once without affecting the merits of the shoe, yet the fullering both enables the shoe to take a firmer hold of the ground, and, when properly executed, serves as a guide to the proper placing of the nail-holes. The advantages of the seated shoe, however, great though these are, have been found insufficient to prevent a number of the most serious diseases of the feet, such as chronic founder, contraction, and grogginess.

Professor Coleman, at the commencement of his career, adopted the opinions of La Fosse; and, by a variety of ingenious contrivances, for several of

which he took out patents, he long continued to support them. Finding, at an early period, more difficulty in the practical application of the short shoe than in the principles of it, he chose to make the heels of it extend to the extremity of the crust, at the junction of the bars, keeping the heels sufficiently thin to allow the frog, under ordinary circumstances, to receive a degree of pressure; but as this could not always be obtained, he invented an artificial frog, an iron wedge, of sufficient thickness at its posterior part to extend beyond the level of the shoe, and rest on the frog; so that when the animal stood in the stable, he should by this means rest the whole, or the greater part, of his weight upon the frog. From this it was expected that the foot would become expanded, and contraction be prevented. The shoe, however, after a time was found insufficient to effect these purposes; and, in addition to the thin heels and wedge, clips were added, which were made to press against the junction of the crust and bars, and thus to offer a mechanical obstruction to the contraction of the hoof. But the friction arising from the elasticity of the heels, soon allowing these clips to insinuate themselves into the horn, prevented those advantages which were first expected from them; and to aid this again the heels of the shoes were now bevelled outwards, so that the hoof, resting on this inclined plane, was forced asunder, as it were, at every step.

The frog-bar shoe was next tried; and this, in its various forms, by keeping up continued pressure upon the frog, was expected to have the power, not only of preventing contraction, and removing it when it had taken place, but also of proving a complete protection to weak heels, and a preventive of corns, thrushes, sand-crack, false-quarter, canker, and the like. But, instead of affording the ease or protection expected from it, it proved in many cases a cause of some of the very diseases it was intended to prevent.

The spring-heeled shoe, or the grasshopper, as some London veterinarians wittily called it, was next tried. This differs from the common shoe in being bevelled off towards the heels, on the surface next the hoof, from the quarter to the extremity of the heel; and at the commencement of the slope in the quarter, there is a steel spring, welded or rivetted on, and continued to the heel, so as to form a continued plane with the surface of the hoof. Between the extremity of the spring and the thinned part of the heel of the shoe, a space of about three-eighths of an inch is left; so that when the weight of the posterior part of the heel falls on the spring, it is allowed to descend, and a degree of liberty is thus afforded. "While I agree with the principles upon which this shoe is applied," says Professor Dick, "I do not altogether agree with the construction of the shoe itself. The advantage to be derived from keeping the heel easy, or springing the heel of the shoe, has been long known to working farriers, and such a process has been found to afford relief in many of the evils of the foot. It is effected in two ways,—either by bending the shoe a little from the hoof at the point of the heel, or by cutting away such a portion of the horn as to prevent the heel of the shoe and the heel of the hoof from coming in contact; and in this latter state it will remain, and retain its situation, until the proportion of the hoof is altered by the progress of growth and the friction between the hoof and shoe. Such an adaptation of the common shoe seems to possess all the advantages, without the complexity, of the spring-heeled shoe, namely, keeping the heels easy, assisting in preventing corns, and affording liberty and elasticity to the heels; and where, from the weakness of the quarters, the common shoe cannot be properly supported, it can in almost every instance be obtained by the bar-shoe. But where the frog is much diseased, and both heels and quarters weak, the spring-heeled shoe may be found of service."

The jointed or expanding shoe came into use contemporaneously with the several and successive inventions which followed the introduction of the seated shoe; and it promised for some time to do wonders, but has already passed into almost total desuetude. It is either seated or concave like the common shoe, and has a joint at the toe for permitting the natural expansion of the foot. But its nails, if well fixed, render most of it perfectly inflexible, and cause the joint to act only as a sort of useless hinge; and, if ill fixed, occasion special stress on the crust at the holes, and become loosened, and tend eventually to tear portions of the crust away. A really expanding shoe, on the jointed principle, should have many joints, in a series along the sides and quarters, and would be at once too complicated, too costly, and too frangible for general use.

The unilateral shoe, or shoe of one-sided nailing, was invented by Mr. Turner of London, and possesses some very decided advantages over even the best forms of the concave seated shoe, and has already superseded it in many of the best forges. It is fastened with five nails along one side; and has two clips,—the one in front, and the other between the last and the next-last nail. "This shoe," says Youatt, "is identified with the grand principle of the expansibility of the horse's foot, and of removing or preventing the worst ailments to which the foot of the horse is liable. It can be truly stated of it, that while it affords to the whole organ an iron defence equal to the common shoe, it permits, what the common shoe never did or can do, the perfect liberty of the foot. There can be no doubt that the one-sided nailing has been exceedingly useful. It has, in many a case that threatened a serious termination, restored the elasticity of the foot, and enabled it to discharge its natural functions. It has also restored to the foot, even in bad cases, a great deal of its natural formation,

and enabled the horse to discharge his duty with more ease and pleasure to himself, and greater security to his rider."

Rodway's patent shoe was invented to suit the slippery surface of the wooden pavements which began, some years ago, to be formed in parts of several of the chief towns of the kingdom. It is simply a concave-faced shoe, whose concavity is constantly filled with dirt, and presents so rough a surface to the pavement as to prevent slipping.—Powell's patent shoe was invented for the same purpose as Rodway's, but presents a sharp surface to the pavement.—If horses had constantly to tread such surfaces as those of wooden pavements, they might go without shoes altogether, and enjoy more ease and safety than with the very best shoes which can possibly be contrived.

The shoes of any common kind for the hind feet are stouter at the toe and straighter at the quarters, than those for the fore feet, and, in general, have also the heels turned up to form calkins.—The common hunter's shoe is cut considerably shorter at the heels, and allows less intervening space between its seat and the foot, than the ordinary seated shoe.—The three-quarter shoe wants the inner heel or quarter, and is suitable for a horse when turned out to grass, or otherwise withdrawn from treading a hard surface.—The tip shoe wants both heels, and is used for the same purpose as the three-quarter shoe, and was formerly used also for racers, but has been superseded in the latter application by a light shoe called a plate.

The French method of shoeing has long been much extolled by some British veterinarians; and, in some respects, with reason enough,—in others, more, it would appear, for the sake of fashion and novelty than real advantage. The French shoe is rather broader in the web than the old English one; it is equally thick at every part; the foot-surface of it is concave, the ground-surface convex, and curved upwards at the toe, in order to give the limb, what the French call "the adjusting balance." Altogether, the shoe itself is certainly, in many respects, an objectionable structure; and in no respect is it more so than in the curvature which is given to the toe of it, the principle of which is false, unnatural, and injurious. The French mode of nailing the shoes upon the feet, however, is one deserving attention, both from the facility with which it is practised, and from the preservation which it affords to weak, brittle hoofs, which, by our method, are too frequently done injury to. The holes in the French shoe are punched in that direction which (instead of penetrating the crust longitudinally—in the direction of the fibres of the wall, as is the case in English nailing) gives the nails an oblique direction, forward as well as upward, by which they not only get a stronger hold, but a more secure one, and are more certain in their issue, —their points making their exit but a little way above the shoe itself; and this method of nailing is not confined to the French, but prevails over all the Continent.

The Persian, Turkish, and Arabian shoes, bear a common resemblance to one another. A horse-shoe of these countries consists of a thin plate of iron, which is said to be hammered into form without being heated. It has a small circular hole in the middle, but for which it would entirely cover the lower surface of the hoof. The outer surrounding border forms a projecting edge downwards; and along its inner circle are eight nails, ranged in fours, laterally, and rather near to one another. The shoe also has a curvature both at toe and heel.—The Barbary shoe differs but little, and very unimportantly, from the Asian productions. The striking character of it is, that the hole in the middle, instead of being circular, is triangular.—The bar-shoe seems to have been formed on the type of the Asian shoes, but is used in Britain only in cases of disease. See the article Bar-Shoe.

The comparative weight and size of shoes are of fully as much importance as their form, and ought to be as nicely adapted as possible to the strength, bulk, character, and work of the horse. A weak foot should never wear a heavy shoe; a small foot should never wear a large one; a horse on light work or constantly on soft ground should never wear as heavy a one as the same horse on severe work or constantly on hard ground; a horse with peculiarly shaped feet should never wear one of the ordinary or normal shape, unadapted to the specialities in the foot's configuration; and a horse of comparatively rapid motion and slight performance should never wear as heavy a one as a horse of comparatively slow motion and laboured performance. According to the estimate of Professor Coleman, the shoe of a large draught horse, on the average, should weigh 2 lb. 10 oz., that of a small draught horse 1 lb. 10 oz., that of a large coach horse 1 lb. 10 oz., that of a small coach horse 1 lb. 4 oz., that of a saddle horse 1 lb. 4 oz., and that of a racing horse 5 oz.

The mode of putting on the shoe, and particularly the proper paring of the hoof for its reception, are also of as much importance as its form. "Many," says White, "have attended chiefly to the form of the shoe, and not to its application, or to the hoof; and this error has done more mischief, and made more enemies to the Veterinary College, than all the prejudices and calumnies of grooms and farriers. The first thing to be attended to is to take away, with the butteris, a portion of the sole between the whole length of the bars and crust with a drawing knife; for the heels of the sole cannot receive pressure without corns. To avoid this, the soles should be made concave, so as not to be in contact with the shoe. If there be any one part of shoeing more important than the rest, it is this removal of the horn be-

tween the bars and crust. When this is done, the horse will always be free from corns, whatever be the form of the shoe. Beside this, the heels of the shoe should be made to rest on the junction of the bar with the crust. If a shoe does not leave ample space for a picker to be passed under it, either the shoe or the sole should be made more concave. When the sole appears in flakes and thick in substance, it will be better to make the sole sufficiently hollow to admit of the application of a flat shoe, as it will rest only in that case on the crust. But when the sole will not allow of being thus pared, the shoe must then be made sufficiently concave on the surface next the foot, that the picker may be passed easily under it. But even in flat or convex feet, the horn is generally sufficiently strong towards the heels to allow of being pared moderately and made concave. In shoeing the hind foot, it will be sufficient to pare off the horn from the sole, and make an even surface for the shoe, which may always be flat on both surfaces; as no inconvenience would arise if it happen to bear a little on the sole. It is usual to turn up one or both heels of the hind shoe to prevent slipping. This should not be done unless the horse is worked in situations which render it necessary; and then the outer heel only should be turned up, and the inner heel made thicker than the toe and quarter, so that both heels may be equal."—See the articles Foot, Paring the Hoof, Navicular Bone, Grogginess, and Founder.

SHOODS. Oat hulls.

SHOREWEED,—botanically *Littorella Lacustris*. A beautiful, perennial, herbaceous, subaquatic, indigenous plant, of the plantain family. It inhabits wet sandy places on the shores. Its root is tap-shaped and fleshy, and throws up many long, linear, channelled leaves; and its flowers have a whitish-green colour, and bloom from June till August. Some flowers on any one plant are barren, and others fertile; and the barren ones have long tremulous stamens.

SHORT-HORNS. See Cattle.

SHOT-OF-BLOOD. See Inflammatory Fever.

SHOULDER. The shoulder of the horse demands the special study of both the breeder and the veterinarian. The muscles of it must be bulky enough to confer a considerable degree of power, and to maintain a sufficient continuance of exertion; but they should not be so bulky or mis-shapen as to give the shoulder a loaded appearance; and those of all saddle-horses should increase from the neck backward with such imperceptible gradation as to make neck and shoulder seem to be of one piece. The two bones, the scapula and the humerus, should stand, not on a straight line to each other, but obliquely,—the scapula inclining so far backward that the lower end shall meet the humerus in a slanting direction; for when they are thus adjusted, they obviate concussion and greatly facilitate all the actions of the limb, and conduce to rapidity of motion, and render the paces of the animal eminently smooth and safe. A horse with an upright shoulder has always a comparatively large supply of humeral muscle, and is thick and cloddy about the upper part of the neck, and must, in consequence, be proportionally heavy, ill-going, and unsymmetrical in all the actions of the fore-part of his body.

A lameness or sprain in the shoulder of the horse is not infrequent. The most common cause of it is a mis-step or some twist or outstretch in action. It is situated too deep to show itself by any external signs upon its immediate seat, or to be discoverable by means of anything which can be seen or felt there; and is indicated principally by the peculiar gait of the animal, or by the dragging of his toe and the circuitous fling he gives the limb in action, corroborated by the absence of any other visible or assignable cause for the lameness. If a doubt exist as to whether the evil be in the shoulder or in the leg or in the toe, an expression of great pain on the horse's part when the foot of the affected limb is lifted and then brought considerably forward will decidedly indicate the lameness to be in the shoulder. The proper remedies are the drawing of blood from the vein on the inside of the arm, the giving of a dose of physic, the application of fomentations on the inside of the arm close to the chest, the keeping of the animal quiet and comfortable, and, if all these remedies prove insufficient, in the course of eight or ten days, the blistering of the whole surface around the point of the shoulder by means of an infusion of cantharides applied without removing the hair.

SHOVEL. A hand-implement of the spade kind, used for collecting and lifting. It differs from a true spade in having a broader and thinner blade, and in not being used for cutting and digging. Several varieties of it are used on the farm, for widely different purposes, and differing from one another in the size, form, and material of the blade. The barn shovel is the most remarkable, and generally has the blade of wood, sometimes edged with iron.

SHOVELER, — scientifically *Anas Clypeata*. A winged winter visiter of Britain, belonging to the swan group of palmipede birds. It is called also the broad-bill and the blue-winged shoveler. Its total length is about 20 inches. The head and the upper part of the neck of the adult male is green; the lower part of the neck is white; and the other parts of the body display mixtures and shadings of white, pale blue, dark brown, and other colours. The shoveler frequents lakes, rivers, marshes, and muddy shores; and feeds on grasses, herbs, worms, insects, and small aquatic animals; and selects its food in shallow water.

SHOWEL. A blind for a cow's eyes.

SHREW, — zoologically *Sorex*. A genus of small carnivorous mammals, somewhat allied to

the moles. They live in holes which they dig in the earth, and seldom leave them till the evening; and they feed on insects and worms. They are covered with hair, and have on each flank a small band of stiff, thickly-set setæ, and discharge from that part of their body, during the rutting season, an odorous humour. The shrew mouse or common shrew, *Sorex araneus*, is grey above and ash-coloured below, and has white teeth, exposed ears, and square tail. It occurs in fields, meadows, and similar situations. It has been accused, but falsely, of producing a disease in horses by its bite. Cats kill it, but will not eat it.—The water-shrew, *Sorex fodiens*, is rather larger than the common one; and is black above and white below; and has red-tipped incisors, partially hidden ears, and a terminally compressed tail. It frequents the banks of brooks, and has amphibious habits. It is very rare in Britain, and was at one time supposed, though incorrectly, to have been exterminated.

SHRIKE,—zoologically *Lanius*. A genus of birds of the dentirostrous tribe of passerinæ. Their bill is triangular at the base, and compressed on the sides. They live in families, and build neatly on trees, and imitate part of the song of musical birds in their vicinity, and fly irregularly and precipitately, uttering shrill cries.

The great grey shrike, or great butcher-bird, *Lanius excubitor*, is as large as a thrush, ash-coloured above, white below, and black in the wings and tail, and has a black band round the eye, and some white on the scapulars, on the base of the wing-quills, and on the external edge of the lateral tail-quills. It remains in France throughout the year, but is only an occasional visiter in England, chiefly between autumn and spring. It feeds on mice, shrews, frogs, lizards, small birds, and insects; and first kills its prey, and then transfixes it on a thorn or on some similar object, and then tears it thence piecemeal.

The flayer or small butcher-bird or red-backed shrike, *Lanius colluris*, has a total length of about 7½ inches. It is ash-coloured on the head and the rump, fawn-coloured on the back and the wings, whitish below, black on the wing-quills with an edging of fawn-colour, and black in the tail-quills, but white on the base of the lateral ones, and it has a black band over the eye. This species has similar habits of treating its prey to the preceding, and hence shares with it the popular name of butcher-bird.

The woodchat shrike, *Lanius rufus*, resembles the flayer in size, in mode of feeding, and in most of its habits; but it differs in plumage, and is of rarer occurrence. Its forehead, its back, its wings, its wing-coverts, and the space round its eyes are black; the top of its head and of its neck is livid red; and its throat, its breast, its belly, and other parts are white.

SHRUB. A low, bushy, ligneous plant, differing from a tree, not only in lowness of stature, but in denseness of habit and in feathering down to the ground,—either sending up several stems from the root crown, or commencing its ramifications from one stem immediately above the surface of the ground. Good examples of hardy, common shrubs are furze, juniper, and holly.

SHRUBBERY. An ornamental collection of shrubs and dwarf trees, or a pleasure-ground, of the size and nature of a garden, decorated principally with these plants. The construction of a shrubbery, both as to disposition of the ground and as to selection of the shrubs, is exceedingly various, and depends much on taste and on the nature of the locality, yet ought to be determined, on the whole, by the general principles of landscape gardening. See the article Landscape Gardening.

SHRUBBY TREFOIL, — botanically *Ptelea*. A small genus of ornamental shrubs, of the terebinth family. The three-leaved species, *Ptelea trifoliata*, is a native of Virginia and Carolina, and was introduced to Britain near the beginning of last century. It commonly attains a height of about 10 or 12 feet. Its branches are not very numerous, and are brittle, full of pith, and covered with a smooth purplish bark, and, when broken, emit a strong scent; its leaves are trifoliate, and stand on long footstalks, irregularly on the branches; its folioles are oval, spear-shaped, and pretty large when fully out, and have a pleasant, strong green colour above, and a lighter colour and smooth surface below, and are late in exfoliating and in attaining their full size; and its flowers come out in bunches at the end of the branches, and have a whitish-green colour, and bloom in June and July. This plant thrives in any common soil, and may be propagated from either seeds, cuttings, or layers.

SHUCK. A husk or shell; also, a shock or stook of twelve sheaves.

SHUGGING. The shedding of the seeds of over-ripe grain at harvest.

SHYING. A horse's starting suddenly aside, either from skittishness, from fear, or from the force of habit. One cause of it is mere constitutional or mischievous playfulness; another is oddity or frightsomeness in strange objects or new circumstances; another is the recollection, by association of place or otherwise, of cruelty or accident; and a fourth is dimness of sight or incipient blindness, induced by advanced age or by disease. Combined firmness and kindness is the proper treatment of the evil when arising from either the first, the second, or the third of these causes; and discrimination and encouragement, even more than firmness, when it arises from the last. Severity, in every case, is very injurious; and caressing, in most cases, is bad. No more, in most instances, should be done with a saddle horse in the act of shying than to employ sufficient steadiness of hand for the effecting of due restraint.

SIBBALDIA. A genus of curious, herbaceous, small, alpine plants, of the rosaceous order. The procumbent species, *S. procumbens*, grows wild and plenteously on the micaceous soils of the lofty mountains of the Scottish Highlands. Its root is perennial; its stems are spreading, cylindrical, from one inch to three inches long, and clothed with coarse upright hairs; its leaflets are wedge-shaped, from half an inch to one inch long, and of a bright green colour; and its flowers grow in corymbose leafy tufts, and have small petals and large hairy calyxes, and are of a yellow colour, and bloom from June till August. The whole plant is astringent.—Two exotic varieties have been introduced from respectively Switzerland and North America; and three hardy, perennial-rooted, erect-growing species, of from 4 to 12 inches in height, have been introduced from other countries.

SIBERIAN PEA-TREE. See CARAGANA.

SIBTHORPIA. A small genus of curious, small, herbaceous plants, of the figwort order. The European or creeping sibthorpia, or Cornish moneywort, *S. europœa*, grows wild in watery shady places, about springs and brooks, in the south of England. Its roots are perennial, woody, and fibrous; its stems are prostrate, creeping, entangled, branched, wide-spreading, slender, delicate, and minutely hairy; its leaves are stalked, alternate, rounded, light green, and rather succulent; and its flowers are axillary, solitary, minute, and white, and bloom in July and August. This plant may be artificially propagated by division, and grown in moist peaty soil.

SICKLE. A hook-shaped hand-implement for reaping corn. It is commonly called in Scotland a reaping-hook, or simply a hook or heuk. It varies, in different districts, and from different manufactories, in size, form, weight, edge, temper, and the quality of the material; but, in a general view, belongs to one of two classes,—the smooth and the serrated. A good smooth sickle weighs 1 lb., and has a cutting edge of 20 inches in length, and is mounted with a beech or plane-tree handle of about 6 inches in length and 4½ inches in circumference; and a good serrated sickle weighs about 9 oz., and has a cutting-edge of 16 inches in length, serrated to the depth of $\frac{1}{25}$ of an inch, with about 300 serratures, all pointed backward or toward the handle. See the articles SCYTHE, HAINAULT SCYTHE, and REAPING.

SICKNESS (THE). See BRAXY.

SICYOS. A genus of annual, climbing, yellow-flowered, culinary plants, of the gourd family. Five hardy species, all similar in habit and appearance to cucumbers, and naturally blooming from July till September, have been introduced to Britain from Continental America and the West Indies. They are popularly called single-seeded cucumbers. They either propagate themselves, or may be artificially propagated, from seeds; but they are too rambling and spreading for small gardens, and ought to be assigned a place near a hedge on which they may climb.

SIDA. A large genus of exotic plants, of the mallow family. About 120 species have been introduced to Britain; and at least 80 more are known. But they possess little floral or economical importance compared to their numbers; and, in the great majority of instances, attract the attention only of botanists. Some are annuals, a few biennials, some herbaceous perennials, and some evergreen shrubs. Among the prettiest of the annuals, are *S. juvenalis* and *S. Csereii*, both white-flowered; of the herbaceous perennials, *S. altaica* and *S. stylosa*, yellowish-flowered, and *S. regia* and *S. virginica*, scarlet-flowered; and of the evergreen shrubs, *S. rosea*, rosy-petaled, *S. inœqualis*, white-flowered, and *S. aurea*, golden-flowered or orange and red flowered. The poplar-leaved species, *S. populifolia*, a yellow-flowered annual of about a foot in height, introduced to Britain about 52 years ago, grows wild in India, and is much used there, by both natives and Europeans, as a medicinal plant,—a decoction of its leaves in the way of emollient fomentation, the expressed juice of them as a cooling remedy in gonorrhœa, and an infusion of the root as a drink in fevers. The root of the lance-leaved species, *S. lanceolata*, has an appearance not unlike that of common liquorice, but is intensely bitter; and it is used in India as a stomachic, as a good remedy in chronic bowel affections, and, in infusion along with ginger, in cases of intermittent fever. The chewed leaves of the hornbeam-leaved species, *S. carpinifolia*, a yellow-flowered, evergreen shrub of 3 feet in height, introduced to Britain upwards of 70 years from the Canaries, allay the inflammation occasioned by the sting of wasps. The straight shoots of the small-flowered species, *S. micrantha*, are used at Rio Janeiro as rocket-sticks. The abutilon or broad-leaved species, *S. abutilon*, is cultivated in India and China for the fibre of its stems, and has even been somewhat extensively introduced into the field culture of Italy and the south of France, and may possibly become so acclimated and productive as, at no distant day, to deserve well the attention of farmers in the south of England. It is a native of both the West Indies, of the East Indies, and of China, and was introduced to the hothouse collections of Britain toward the close of the 16th century. Its roots are annual; its stems are generally simple and from 3 to 5 feet high; its leaves are stalked, broadly cordate, pointed, dentated, and slightly downy; and its flowers are small, and have a simple angular calyx and a pale yellow corolla, and naturally bloom from June till August. This species, also, is the type of a somewhat recently constituted genus, which takes the name of abutilon, and comprises all the species of the old genus sida which have many-seeded carpels,—

leaving only those species to be still called sidas which have one-seeded carpels.

SIDERITIS. See ALL-HEAL (CLOWN'S).

SIDEROXYLON. See IRON-WOOD.

SIDESADDLE-FLOWER. See SARRACENIA.

SIEGESBECKIA. A genus of curious and ornamental, exotic, annual plants, of the sunflower division of the composite order. Six species, chiefly yellow-flowered and about 2 feet high, and all late in blooming, have been introduced to Britain from Mexico, Peru, Iberia, and India.

SIEVE. An implement for separating smaller particles from larger ones. Sieves of many kinds are used in not a few departments of the useful arts, chiefly for separating finer grains or powders from coarser ones; and sieves of several constructions and of different varieties are used on the farm for separating cereal grain and other seeds from dust and general impurities. Most sieves are textures of basket-work, wire, gut, or hair, stretched on a broad wooden hoop; but some consist of perforated and stretched skins or iron-plates; and a few, for very fine work, particularly in the pharmaceutical processes of the druggist and the practical chemist, consist of lawn or other fine cloth stretched within high, thin, circular frames. Barn sieves require to be of different capacities for respectively beans, wheat, oats, rape-seed, and other produce. An excellent complex implement, called a seed-sifter, and well adapted for the separating and cleaning of ryegrass seeds, was invented about 12 years ago by Mr. Leckie of Haddington, and is modelled in the Museum of the Highland Society, and described and figured in the 12th volume of their Transactions. It contains three wire sieves, of different width of mesh, and is worked by means of a winch-handle and connecting machinery. "The rough seed is put into the upper sieve, which, by agitation, allows the ryegrass and smaller seeds to pass through, while husks and larger seeds are retained. The former are received upon the middle sieve and subjected to a second separation in which the fine ryegrass, dust, and small seeds only are passed through. These falling upon the lower or sloping sieve, are again separated, the dust and small seeds fall through this as waste, and the ryegrass seed in a clean state is discharged over the lower edge."

SIEVERSIA. A genus of ornamental, hardy, perennial-rooted, yellow-flowered, herbaceous plants, of the rosaceous order. Six or seven species, all but a few inches in height, and blooming from about midsummer till some time in autumn, have been introduced to Britain from North America, Continental Europe, and Siberia; and they, for the most part, love a soil of peaty loam, and are propagated by division.

SIFTING. The separating of seeds from impurities, or of smaller particles from larger, by means of implements. See the articles SIEVE, SCREEN, and THRASHING-MACHINE.

SILAUS. See PEPPER SAXIFRAGE.

SILENE. See CATCHFLY.

SILEX. See SILICA.

SILICA. The oxide of silicium. It possesses great interest to the chemist, on account of its remarkable affinities and reactions,—to the geologist, on account of its vast predominance in many kinds of rock, or of its constituting a very large portion of the crust of the world,—to the mineralogist, on account of its being the chief ingredient in many gems and other rare and beautiful minerals,—to the phytologist, on account of its forming an essential part of the food of plants,—and to the agriculturist, on account of its intimate connexion with the offices of soils and manures.

Silicium or silicon is a simple body, belonging to the same group of elements as carbon and boron. It does not naturally exist in an uncombined state; and was first demonstrated to be a distinct body by Sir Humphrey Davy; and first obtained, in a pure separate state, in 1824, by Berzelius. It may be prepared in several ways,—but, most conveniently by decomposing highly dried double fluoride of silicium and potassium or sodium, and afterwards driving off some combined hydrogen and some adhering silica. It is a dark nut-brown substance, perfectly destitute of metallic lustre, a non-conductor of electricity, incombustible in air or in oxygen, infusible by the flame of the blow-pipe, and insoluble in sulphuric, nitric, muriatic, or hydrofluoric acid, but vividly combustible in contact with carbonate of potash or soda, deflagrable in mixture with nitre under a high temperature, and explosible by being dropped upon fused hydrate of potash, soda, or baryta.

Silica or silex is one of the most abundant earthy substances in the world. It forms a great proportion of the primitive rocks; it is the chief ingredient in sandstones; it constitutes by far the main part of quartz rock, and is nearly identical with flint; it forms from 50 to 70 per cent. of the total bulk of most barren soils, and from 50 to 85 per cent. of the total bulk of most fertile soils; and, under a great variety of slightly modifying circumstances, it constitutes almost the entire substance of calcedony, agate, jasper, rock crystal, and other analogous gems. It may be obtained in comparative purity by throwing red-hot pieces of transparent rock crystal into water, and afterwards pulverizing them; and, as thus obtained, it is a light, white, insipid, inodorous powder, rough and dry when rubbed between the fingers, totally insoluble in water, fixed or quite infusible in the fire, but more readily fusible than lime or magnesia before the oxyhydrogen blow-pipe. It is not acted on by any acid except the hydrofluoric; but it dissolves in solutions of the fixed alkalies, and combines with many of the metallic oxides. Silica itself, though incapable of acid reaction upon vegetable colours, claims, in reference to its behaviour with

alkaline bodies, to be called silicic acid; and the many earthy combinations of it with potash and soda and lime and magnesia and other salifiable bases in rocks and soils and gems, must be regarded as true salts or native silicates. Several of the varieties of silica itself, but especially all the most common salts of it, or most abundant native silicates, occur both naturally and artificially, under modifications or in contact with substances or in exposure to agencies, which completely subdue its refractoriness and insolubility, and render it facilely and abundantly available for absorption by plants.

"Quartz," says Liebig, "forms a very pure variety of silica, and, in this condition, it is quite insoluble both in cold and in hot water, is without taste, and does not exert any action on vegetable colours. The principal property of silica in this state is, that it unites with alkalies, forming saline compounds, which are termed silicates. Window and plate glasses consist of mixtures of silicates of the alkaline bases, potash, soda, and lime. In such compounds, the alkali is generally completely neutralised. The property of neutralising metallic oxides and alkalies belongs only to acids; and it is owing to this that silica has received the name of silicic acid. Silica is a very feeble acid, for, in its crystallised form, it is destitute both of taste and of solubility in water; but it dissolves by continued digestion in alkaline leys. We may easily obtain compounds of silica with potash and soda, by melting it either with a pure alkali, or with an alkaline carbonate. By this treatment, white glasses are obtained, differing in properties according to their amount of soluble ingredients. When the glass contains 70 per cent. of silica and 30 per cent. of potash or soda, it becomes soluble in boiling water. Its solution may be spread over a surface of wood or of iron, and then dries into a vitreous substance, which has received the name of soluble glass. When there is a smaller proportion of alkali than the above quantity, or, in other words, when there is a larger proportion of silica, the resulting glass diminishes in solubility in a greater or less degree. All silicates soluble in water are decomposed by acids. If the solution of the silicate contains silica corresponding to more than $\frac{1}{30}$ the weight of the water, the addition of an acid causes the formation of a precipitate of a very gelatinous appearance. This precipitate, being a compound of silica with water, is termed the hydrate of silica. But, if the solution contains less silica than the above proportion, no precipitate is formed on the addition of an acid, the whole remaining perfectly clear. This circumstance proves that silica, in the state in which it is precipitated by an acid, possesses a certain degree of solubility in pure water. Indeed, by washing with water the gelatinous precipitate of silica, its volume diminishes, and silica may be detected in solution by evaporating the water which has passed through. From these facts we perceive, that silica possesses two distinct chemical characters. In the form in which it is separated from a silicate, it possesses quite different properties from those which it has when in the state of sand, quartz, or rock crystal. When sufficient water is present during its separation from a base, to effect its solution, the whole remains dissolved; in certain conditions, silica is more soluble in water than gypsum. On drying, silica loses almost completely its solubility in water. The solution of silica in acids acquires, at a certain degree of concentration after cooling, such a gelatinous consistence that the vessel containing it may be turned upside down without spilling a drop of the transparent jelly. By drying it still further, the water which retained it in the gelatinous condition, escapes along with that which had served to hold it in solution. When the water has been once removed in this way, the silica is no longer soluble in water. But, although it has thus lost its solubility, it does not acquire all the properties of crystallised silica, such as sand and quartz, for it still possesses the power of dissolving in alkalies and alkaline carbonates at the ordinary temperature of the air, and this power it retains even when it has been heated to redness. There is scarcely any other mineral substance which can be compared to silica for the possession of such remarkable properties as those now described.

"Most of the insoluble silicates containing alkaline bases are decomposed by the action of hot water, particularly when that water contains an acid. In the middle of the last century, the ignorance of this fact led chemists to believe that water might be converted into an earth. When water is distilled in glass vessels, it is found to contain always a certain quantity of earthy substances, which may be detected by evaporation, even if the water has been subjected to many repeated distillations. Lavoisier proved that part of the glass was dissolved in this operation by the boiling water; and further, that the diminution in the weight of the glass vessel corresponded exactly to the quantity of earthy residue left by the evaporation of the water. When the distillation of water is effected in metallic vessels, no such residue can be obtained. The action of water upon the silicates contained in glass may be observed in the opacity which gradually comes over the windows of hot-beds, these being exposed in a great degree to the influence of the air. This action is more marked in the windows of stables, where the carbonic acid formed by the processes of respiration of the animals, and by the decay of animal matter, accelerates the decomposition.

"Silica being an acid of a very feeble character, the decomposition of the soluble silicates is effected even by carbonic acid. A solution of soluble glass may be converted into a gelatinous

mass by saturating it with carbonic acid gas. The same decomposition must take place in very dilute solutions, although we cannot detect in them any separation of silica, which remains dissolved in the water. The decomposition of silicates by the combined action of water and of acids proceeds with a rapidity proportional to the quantity of alkalies contained in them. We find numerous examples in the inorganic kingdom of a continued and progressing process of decomposition of the silicates contained in the various kinds of rocks; this decomposition is effected by the action of carbonic acid and of water.

"A consideration of the preceding observations shows clearly that porcelain clay or kaolin has been formed by the decomposing action of water on the silicates of potash and soda contained in felspar or felspathic rocks. Felspar may be viewed as a combination of silicate of alumina with silicate of potash; the last of which, being gradually removed by water, leaves behind the porcelain clay. It has been shown by Forchammer, that felspar may be decomposed by water of 302° F., and at a pressure corresponding to this temperature. The water becomes strongly alkaline, and is found to contain silica in solution. The hot springs in Iceland possess a high temperature, and come from a great depth, where they must have been subjected to high pressure. Forchammer has shown by analysis that the water of these springs contains the constituents of soda felspars, and of magnesian silicates, minerals of very frequent occurrence in trap districts. There cannot be a doubt that a conversion of crystalline felspar into clay must be proceeding to a great extent at the bottom of these springs. Ordinary water containing carbonic acid acts in precisely the same manner as water at a high temperature, and at a high pressure. Polstorf and Wiegmann boiled some white sand with a mixture of nitric and muriatic acids, and after completely removing the acid by washing the sand with water, they exposed it thus purified to the action of water saturated with carbonic acid gas. After the expiration of 30 days, this water was subjected to analysis, and was found to contain in solution, silica, carbonate of potash, and also lime and magnesia; thus proving that the silicates contained in the sand were unable to withstand the continued action of water containing carbonic acid, although the same silicates had resisted the short action of the aqua regia.

"Certain of the alkaline silicates found in nature contain in their crystalline state water in chemical combination. In this class are the zeolites, analcime, mesotype, sodalite, apophyllite, &c.; the felspars, properly so called, are always anhydrous. These silicates differ very much in their behaviour to acid reagents. When mesotype, or a mineral corresponding to it in composition, is kept in the state of a fine powder in contact with cold muriatic acid, it increases in bulk to a thick jelly. The mineral being exposed to the action of the acid at the ordinary temperature, those constituents which are soluble in the acid are taken up by it whilst the greatest part of the silica remains undissolved. Labrador spar (calcareous felspar) behaves similarly when treated with acids; but the minerals adularia and albite (potash and soda felspars) are not attacked by acids under similar circumstances."

Silica, under soluble conditions, is a comparatively large ingredient in the food of agricultural plants, and plays an important part in the fertility of soils. The quantity of it in any one species of plant varies in different parts of the plant, in different varieties of the species, and upon different kinds of soil. The quantity of it, in the mean of six specimens of turnip bulbs, analysed by Professor Wey and Mr. Ogston, amounted to 0·34 lb. per ton; in the mean of six specimens of turnip-tops, to 1·73 lb. per ton; in the mean of six specimens of entire crops of turnips, to 0·55 lb. per ton; in the mean of three specimens of beet-bulbs, to 0·54 lb. per ton; in the mean of three specimens of beet-leaf, to 0·76 lb. per ton; in the mean of three specimens of entire crops of beet, to 0·56 lb. per ton; in the mean of five specimens of carrot-roots, to 0·24 lb. per ton; in the mean of three specimens of carrot leaves, to 4·46 lbs. per ton; in the mean of three specimens of entire crops of carrots, to 1·22 lb. per ton. The quantity of silica, according to the same authority, amounts to 0·61 lb. per ton in the tubers of Jerusalem artichoke, to 1·76 lb. per ton in pease grown on chalk, to 0·84 lb. per ton in pease grown on clay, to 2·53 lbs. per ton in pease straw grown on chalk, to 5·04 lbs. per ton in the entire crop of pease grown on clay, to 1·94 lb. per ton in pease straw grown on clay, to 0·42 lb. per ton in beans grown on clay, to 2·61 lbs. per ton in bean straw grown on clay, to 3·17 lbs. per ton in the entire crop of beans grown on clay, to 60·0 lbs. per ton in wheat straw, to 172·1875 lbs. per ton in wheat chaff, and to 16⅜ oz. in every 28 bushels or 1,792 lbs. of wheat grain. Two important practical inferences from these facts, are, that the root crops bring up soluble silica from the deep parts of the soil, or assist the subjugation of crystalline silica under soluble condition in the higher parts of the soil, in preparation for the uses of the corn crops,—and that by far the major portion of all the soluble silica abstracted from the soil by a whole course of crops, may be returned to it in the leaves or tops of the root crops and especially in the straw and chaff of the grain crops. A main office which silica appears to perform is to give mechanical firmness and strength and resistiveness to the parts and organs of plants which are most exposed to the risk of fracture or postration or other injury from the weather; and therefore it is scarcest in the pulp or farina of seeds and in

the flesh of succulent roots, less scarce in leaves, more abundant in culms, and most plentiful in the sheltering chaff-coats of the ripening grain.

The quantity of soluble silica in most soils, or of silica under conditions which render it capable of solution and readily available for the use of plants, is so great as to render special applications of it altogether unnecessary. The small proportion of it, too, which is carried off by the seeds of field crops, and not returned in the portions of farm-yard manure which consist of leaves and culms and chaff, is, in general, far more than compensated by the disintegration of part of the insoluble silicious constituents of the soil in the operations of fallowing and tillage, and by the bringing up of soluble silica from the lower parts of the soil in the absorptive process of root crops, and allowing it to remain on the field by carrying away only their bulbs or tubers or taps. "Between corn crops," as Liebig suggests, "we may grow mangel-wurzel or even potatoes, if we remove only the tubers of the latter, and allow the plant itself, which contains much silica, to remain on the field." But, in fact, most fields contain such a large natural store of available silica, that no care respecting it needs to be entertained, and no expedient for any special supply of it needs to be adopted, for centuries to come. Almost the only soils, or at least the chief ones, which may now and statedly require direct applications of it, are peat lands and other predominantly humous grounds, which contain a comparatively small proportion of mineral matter, and which produce such soft and flexuous corn-culms as want sufficient strength and firmness to resist the buffetings of the weather. Yet many scientific farmers, and even some distinguished agricultural chemists, contend that artificial silicates should be applied to all soils,—that they form an indispensable ingredient in any compound special manure which is intended to serve as a substitute for farm-yard manure,—and that they form a fit and sometimes necessary preparation for a wheat crop on any land which has suffered an appreciable abstraction of its soluble silica by the crops of the immediately preceding years. The question thus brought into dispute is one of very considerable practical importance, and requires much knowledge and very comprehensive thought for its proper investigation. Let us hear the reporter of the Agricultural Chemistry Association of Scotland upon it:—

"It may be said by some that guano and bones are both alike deficient in silica, which exists so largely in our grasses and in the stems of our corn plants; and, therefore, that some soluble silicate might with advantage be added to either of these manures, when crops of corn are to be improved by them. There is much show of reason in this when considered theoretically, and there are, no doubt, cases in which an admixture of one-fifth of its weight of silicate of soda would improve a guano, or in which the use of sulphated bones for the turnip crop might be beneficially followed by a top-dressing of silicate of soda upon the young corn of the following year. But the propriety of incurring the expense of such an application along with bones in all cases is very doubtful. Here also much will depend upon the actual constitution of the soil; for it would be a waste to add anything which the soil already contains abundantly, and in a state in which it can readily minister to the wants of the plant. Now, if a portion of soil be burned, in order to destroy the organic matter it contains, and be then boiled in distilled water for a length of time, and the filtered solution be afterwards evaporated to dryness, and the residue heated to redness to burn off the organic matter, a minute but variable quantity of saline matter will remain, in which a trace of silica will usually be found. Most soils, therefore, contain some silica in a state in which it may be taken up by water. Again, if, after boiling with water, the soil be digested for two or three hours with concentrated muriatic acid till it is perfectly colourless, and if the filtered solution be treated with ammonia and oxalate of ammonia, to separate the oxide of iron, alumina, and lime, and be then evaporated to dryness, an appreciable quantity of silica will be found in the saline matter which remains. Or, if the acid solution be at once evaporated to dryness, and then treated with water, some silica will remain insoluble. Soils, therefore, generally contain a further appreciable quantity of silica, in a state in which it is soluble in acid solutions." He then states that, of five specimens of different soils which he analyzed, one contained 0·19 per cent. of silica soluble in acid solutions, another 0·16 per cent., a third 0·2 per cent., a fourth 0·17 per cent., and the fifth at top 0·84 per cent., and at bottom 0·42 per cent.; and he adds:—"I could have given many other such results; but these show both the presence of silica in this state in our cultivated soils, and how much it varies in different soils. The quantity present in the first and third instances—1-5th of a per cent., or one pound in 500 lbs. of soil—appears very small when compared with the whole soil, and yet it proves to be large when we come to calculate how much an acre of soil will contain, and how much a crop of corn will carry off from that acre. A square yard of soil 12 inches deep, will weigh about 700 lbs., so that this extent of soil will contain 1⅔ lb. of silica soluble in acids, which amounts to 6,700 lbs. in an acre! The straw of our grain crops leaves, on an average, less than five per cent. of ash, of which less than one-half usually consists of silica, and a crop of straw rarely exceeds 3,000 lbs. per imperial acre. If we take these numbers as tolerable approximations, the quantity of silica carried off by a crop of straw amounts to 75 lbs. per acre, while the silica soluble in acids, and which it is be-

lieved plants can take up, amounts, as above, to 6,700 lbs. Or this silica will alone supply the wants of 900 crops of corn. The soil in the fifth instance contains four times as much, or it would provide silica for 3,600 crops!—Further, if the insoluble portion of the soil be washed with water, to free it from siliceous sand, and the finer or clayey part be collected and fused with carbonate of soda, and then treated with muriatic acid, a large portion of silica, in light white flocks, will remain behind; while the solution will contain alumina, lime, magnesia, and perhaps potash and soda, with which the silica had been combined in the soil. This portion of the silica of the soil is very large, and sometimes forms nearly one-half of its whole weight. In the form of silicates insoluble in muriatic acid, therefore, the soil contains an enormous quantity of silica. There can be no doubt that the roots of our corn crops are capable of taking up and appropriating that portion of the silica of the soil which is soluble in water, but it may be doubted by some if that which is taken up by acids, and especially if that which acids leave undissolved, is capable of supplying the wants of our growing crops. I will not offer here any of those theoretical considerations which induce chemists and physiologists to believe that both the silicates which are soluble and those which are insoluble in acids, are really a source of mineral nourishment to the plant. An appeal to experiment will be much more satisfactory to the practical man. Wiegman and Polstorf took fine white quartz sand, burned it to destroy any organic matter it might contain, digested it for 16 hours in strong nitro-muriatic acid, and then washed it with distilled water. Everything soluble being thus removed, seeds of different kinds, barley, oats, buckwheat, vetch, clover, and tobacco were sown in it, and watered with distilled water. They all grew and came to a greater or less height. The ash left by separate portions of the seeds and plants, when full grown, was determined and analysed. In the following table I have put together their comparative results, in so far as the silica is concerned, as well as the height to which the plants had arrived when they were gathered:—

	HEIGHT.	SILICA IN THE ASH		SILICA had increased.
		Of the Seed.	Of the Plant.	
	Inches.			Times.
Barley, . .	15	0.034	0.355	10
Oats, . . .	18	0.064	0.354	5½
Buckwheat,	18	0.004	0 075	18
Vetch, . .	10	0.013	0.135	10
Clover, . .	3½	0.009	0.091	10
Tobacco, .	5	0.001	0.549	500

Thus it appears that, from quartz sand, after it has been digested in strong acids, plants are able to extract silica as well as other kinds of inorganic nourishment, to which, in the above table, I have not alluded. The sand in which the plants had grown, was found, upon analysis, to contain 97·9 per cent. of pure silica, the remainder consisting of potash, lime, magnesia, alumina, and oxide of iron. From this experiment, therefore, we are justified in concluding that plants are capable of decomposing and extracting silica even from those silicates in the soil which are not attacked by acids. How much more easily may they decompose and appropriate the constituents of those silicates which are capable of being decomposed and dissolved by acids! Nor is it in virtue of any mysterious power that this decomposition is effected. The prolonged action of water containing carbonic acid, slowly decomposes even the most refractory silicates. The water in the soil is more or less charged with this carbonic acid—the decaying vegetable matter of the soil produces it, and the roots of living plants give it off—so that a simple chemical action is sufficient to explain how the plant can obtain food from such unpromising materials. It is an important conclusion, therefore, for practical agriculture, that the silica, which is so necessary to the growth of our corn and hay crops, abounds so much in nearly all our soils, and in a state in which the roots of plants can more or less readily take up. It satisfies us in regard to three points,—as to where and how the plants obtain their silica,—that, in general, it cannot be necessary to add silica in any form as a manure to the soil,—and, therefore, that the broad assertions of those who say that guano or bones should always be mixed with silicate of potash or soda, and who ascribe certain alleged failures of these manures to the absence of such silicates—that these assertions are hastily made and are not to be depended upon. I believe there are very few soils indeed, which, if properly treated otherwise, will refuse to yield good crops merely because a soluble silicate has not been added to them.

"There is only one legitimate purpose for which a silicate should be added to the soil—it is to supply silica to the plant. We ought not to add silicates for the purpose of supplying alkaline or earthy matter, unless some question of economy interferes. We use wood-ashes which contain silicates, because it is cheaper to add potash in this than in any other form. There is only one evidence, therefore, that the addition of a silicate has done good to our corn crop—it must have given more silica, and consequently, as it is believed, more strength to the straw. That the crop has been generally improved, that it is more luxuriant and thriving, or even that it yields a larger return of corn, will not be a proof of the virtue of the silicate. The effect may result from the action of the potash or the soda it contains, and the use of these alone might have produced the same effect. Oats grown upon a mossy soil are soft and dull in the straw, and I have found such straw to be deficient in silica. Wheat growing rankly upon a moist soil, and in a moist season, or a heavy thickly grow-

ing crop of barley, are apt to be laid by the wind, or to fall down under the weight of the ear. The straw is too feeble in all these cases, and it has been said that the use of silicates would abate the evil. Lampadius found the growth of wheat and rye to be greatly promoted by the use of a soluble silicate of potash, but the alkali might be the cause of the effect observed, and no other experiments of an accurate kind have yet been made. It is still an open question, then, whether or not we have it in our power, at our pleasure, to strengthen the straw of our corn plants—whether it would be useful to apply the soluble silicates to all soils—whether there are any to which they may be applied with advantage and profit as an ordinary manure."

SILICATES. See Silica.

SILK. According to the ancients, silk was first brought from Serica or Serinda (China), whence the silk-worm was introduced into other countries, but not until the reign of Justinian, when two Persian monks succeeded in secretly conveying a number of the eggs to Constantinople in a hollow cane (552). From these eggs Europe and America have been supplied with their race of worms. The time of the origin of the silk manufacture is uncertain, but the Chinese ascribe the invention to the empress Si-ling-shi, wife of Hoang-ti, about 2,700 years before the Christian era. However this may be, the raw material had been exported from China long before the insect which produced it, and had given employment to extensive manufactories in Persia, Tyre, &c. The invention of the celebrated Coan stuff is attributed by the Greeks to Pamphila, who is said to have taught her countrywomen of Cos to unweave the heavy silks of the East, and recompose the material into a transparent gauze, thus gaining in measure what was lost in substance. Even manufactured silk was little known in Europe before the reign of Augustus; and it is mentioned as a wanton extravagance of the prodigal Heliogabalus that he had a garment made wholly of silk. For six hundred years the culture of the silk-worm in Europe was confined to the Greek empire; but in the twelfth century, Roger, king of Sicily, introduced it into that island, whence it gradually spread to Italy, Spain, France, and other European countries.

After the worm has enveloped itself in the coccoon, seven or eight days are permitted to elapse before the balls are gathered; the next process is to destroy the life of the chrysalides, which is done either by exposure to the sun or by the heat of an oven or of steam. The coccoons are next separated from the floss, or loose, downy substance, which envelopes the compact balls, and are then ready to be reeled. For this purpose, they are thrown into a boiler of hot water, for the purpose of dissolving the gum, and, being gently pressed with a brush, to which the threads adhere, the reeler is thus enabled to disengage them. The ends of four or more of the threads thus cleared are passed through holes in an iron bar, after which two of these compound threads are twisted together, and made fast to the reel. The length of reeled silk obtained from a single coccoon varies from 300 to 600 yards; and it has been estimated that twelve pounds of coccoons, the produce of the labours of 2,800 worms, who have consumed 152 pounds of mulberry leaves, give one pound of reeled silk, which may be converted into sixteen yards of gros de Naples. Those coccoons which have been perforated cannot be reeled, but must be spun, on account of the breaks in the thread. The produce of these balls, when worked, is called *fleuret*. The raw silk, before it can be used in weaving, must be twisted or thrown, and may be converted into singles, tram, or organzine. The first is produced merely by twisting the raw silk, to give more firmness to its texture. Tram is formed by twisting together, but not very closely, two or more threads of raw silk, and usually constitutes the weft or shoot of manufactured goods. Organzine is principally used in the warp, and is formed by twisting first each individual thread, and then two or more of the threads thus twisted, with the throwing mill. The silk, when thrown, is called *hard silk*, and must be boiled in order to discharge the gum, which otherwise renders it harsh to the touch, and unfit to receive the dye. After boiling about four hours in soaped water, it is washed in clear water to discharge the soap, and is seen to have acquired that glossiness and softness of texture which forms its principal characteristic. The yarn is now ready for weaving.

Velvet (Italian, *velluto*, shaggy) is one of the richest of silken fabrics, and has been made in Europe for several centuries. In addition to the warp and shoot, of which the substance of plain goods is formed, it has a soft shag or pile, produced by the insertion of short pieces of silk under-thread doubled under the shoot, and which stand upright on its upper surface, so crowded together as entirely to conceal the interlacings of the warp and shoot. It is this pile which gives it its characteristic appearance, and softness to the touch. The beauty of velvet results, in a great degree, from the uniform evenness of its pile; and this depends on the perfect equality of the threads of which it is composed. The pile is inserted during the operation of weaving the warp and shoot. Gauze is a very light, transparent fabric of silk, said to have derived its name from having been originally brought from Gaza, a city of Palestine. Besides brocade and damask there are numerous descriptions of silk goods, popularly known by distinctive names, though varying only in the thickness of the fabric or the quality of the material, and not at all differing in the arrangements of its interlacings. Thus the plainest mode of silk weaving takes the

names of Persian, sarsnet, gros de Naples, ducapes, &c., of which the two first are of flimsy texture, and the two last are made of stouter and harder thrown organzine. Satin is a twill of a peculiar description, the soft and lustrous face of which is given by keeping a large proportion of the threads of the warp visible. When first taken out of the loom, satins are somewhat flossy or rough; and they are dressed by being rolled on heated cylinders, which operation gives them their brilliant lustre. Crape is a light and transparent article of plain weaving; Levantine, a stout, close-made, and twilled silk. Gros des Indes is formed by using different shuttles, with threads of various substances for the shoot. The process of watering silk, which gives its surface a peculiar wavy appearance, is performed by passing two pieces of silk, placed lengthwise, one on the other, between two metallic rollers; the different parts are thus subjected to different degrees of pressure, from which the wavy appearance results. Silk is embossed by passing the plain stuff between rollers, the surfaces of which contain the desired pattern, on one cylinder raised, and on the other sunk, so that the eminences of the one coincide with the depressions in the other. Silk also enters into the composition of several mixed fabrics, the most common of which is bombasin, a twilled manufacture, having its warp of silk and its shoot of worsted. Poplins and lustres are plain woven goods, with a larger proportion of silk than bombasins.

The annual value of the silk manufactures in England is stated at £14,000,000. The raw silk is imported to the amount of above 4,000,000 pounds annually, of which 1,500,000 pounds are from Bengal. In 1824, the high duty on raw silk imported was abandoned for one merely nominal; that on thrown silk was reduced nearly one half, and the admission of foreign manufactured goods was rendered legal, after July 5, 1826. In the five years preceding this change, the importation of raw and thrown silk had amounted to 10,925,646 pounds; in the five years succeeding, the total amount of the importation was 18,582,213 pounds. The admission of foreign manufactured silks has also led to a great improvement in the quality of the domestic manufactures. The value of manufactured silks exported from France in 1824, was 100,000,000 francs. Italy supplies England and France with a large quantity of raw silk. Some attention has recently been paid in the United States to the rearing of the silk-worm; great numbers of mulberry trees have been planted in different parts of the Union, and attempts have been made to introduce the manufacture of silks in the country. Several experiments have been made also as to the producing of silk in England; but hitherto they have been very discouraging.

SILK COTTON TREE. See Bombax.

SILK-TREE. The Acacia Julibrissin. See the article Acacia.

SILKWORM (*Bombyx mori*). This seemingly insignificant insect has now become one of the most important to man of all domestic animals. It was originally a native of China, and the neighbouring parts of Asia, and was there bred and domesticated for a long time before it was known in Europe. Now, the manufacture of silk is one of the most important sources of wealth to many parts of that continent. At first, silk stuffs were sold for their weight in gold; but they are now comparatively cheap. The silk-worm is a caterpillar, which, in due time, undergoes its metamorphoses, and becomes a moth, like others of the genus. At birth, and for the first ten days, the colour of the worm is blackish or obscure. As it grows, it casts its skin at stated periods, and turns whitish or bluish, and, when ready to spin, becomes yellow. It is covered with scattering hairs, and has a little fleshy tubercle on the upper part of the last ring. It feeds on the mulberry. Before spinning, it fasts for thirty-six hours, voids all its excrements, becomes soft and flaccid, and seeks a suitable place for the construction of its coccoon. Two or three days are occupied in this work, and the thread is stated by Count Dandolo to be sometimes 625 yards in length. The worm then changes to a chrysalis, and, after remaining twenty days, the moth comes out, forcing its way through the coccoon. The males first appear, and are very brisk in their motions, but do not fly, at least in cold climates. They live but a few days, and the females perish also as soon as they have deposited their eggs. The eggs are attached, often to the number of five hundred, or more, by means of a gummy substance, and hatch in the ensuing spring. The successful rearing of silk-worms is a distinct art, and requires peculiar attention. They are subject to a variety of maladies. In many places, it is usual to import the eggs from some district that has acquired reputation for their production. These are packed like grain, and are chosen much in the same manner. The eggs are in many places hatched by the heat of the human body. The silk is contained, in the form of a fluid, resembling varnish, in long cylindrical sacks, many times the length of the animal, and capable of being unfolded by immersion in water. This fluid is easily forced out, and advantage is sometimes taken of this circumstance to procure threads much coarser than usual, which are extremely strong, and impermeable to water.

SILPHIUM. A genus of hardy, perennial-rooted, yellow-flowered, herbaceous, North-American plants, of the sunflower division of the composite order. About 15 species, varying in height from 2½ to 14 feet, and blooming from about the end of summer till near the beginning of winter, have been introduced to Britain. They are sometimes popularly called bastard chrysanthe-

mums; but though two or three are somewhat ornamental, the majority have the look of mere weeds. They thrive in any common soil, and are propagated by division.

SILVER. A metal which appears to have been known almost as early as gold, and, without doubt, for the same reason, because it occurs very frequently in a state of purity in the earth, and requires but an ordinary heat for its fusion. Mention is made of silver in the book of Job, which is considered the oldest of the books contained in the Old Testament. Pure silver is of a fine white colour, with a shade of yellow, without either taste or smell, and, in brilliancy, is inferior to none of the metallic bodies, if we except polished steel. It is softer than copper, but harder than gold. When melted, its specific gravity is 10·47; when hammered, 10·510. It is next in malleability to gold, having been beaten out into leaves only $\frac{1}{100000}$th of an inch in thickness. Its ductility is no less remarkable. It may be drawn out into a wire much finer than a human hair; so fine, indeed, that a single grain of silver may be extended about 400 feet in length. Its tenacity is such, that a wire of silver 0·078 of an inch in diameter is capable of supporting a weight of 187·13 pounds avoirdupois without breaking. Silver melts when heated completely red-hot; and, while in the melted state, its brilliancy is greatly augmented. If the heat be increased after the silver is melted, the liquid metal boils, and may be volatilized; but a very strong and long-continued heat is necessary. Gasto Claveas kept an ounce of silver melted in a glass-house furnace for two months, and found, by weighing it, that it had sustained a loss of one-twelfth of its weight. When heated upon charcoal under the flame of the compound blow-pipe, however, the silver is volatilized with rapidity, passing off in a visible smoke. When cooled slowly, its surface exhibits the appearance of crystals; and, if the liquid part of the metal be poured out as soon as the surface congeals, pretty large crystals of silver may be obtained. Silver is not oxidized by exposure to the air; it gradually, indeed, loses its lustre, and becomes tarnished; but this is owing to a different cause. Neither is it altered by being kept under water. But, if it be kept for a long time melted in an open vessel, it gradually attracts oxygen from the atmosphere, and is converted into an oxide.

SILVER FIR,—botanically *Picea*. A genus of trees of the pine division of the coniferous order. It was included first in the old genus pinus, and next in the later genus abies; and it possesses a somewhat close affinity to the present genus abies, or spruce fir, by its leaves being flattened and more or less pectinated and all turned toward one side, and by its seeds being irregularly shaped and more than half surrounded by the winged persistent pericarp.

The common or pectinate silver fir, *Picea pectinata*—formerly called *Pinus picea* and *Abies picea*—is a native of the mountains of northern Asia and northern Continental Europe, and was introduced from Germany to Britain about the beginning of the 17th century. Its stem is tall; its form is pyramidal; its branches grow horizontally and in regular whorls; its bark is light-coloured and smooth; its leaves are pectinate, smooth, flattened, dark green, rather upwards of an inch in length, and rounded or very slightly indented at the point, and have one deep central channel on their upper side, and two silvery channels on their under side; its male catkins are stalked and shortly cylindrical; its cones are erect, cylindrical, from 4 to 6 inches long, fully one inch in diameter, and of a purplish colour in most varieties but white in some; its scales are rounded, very broad, incurved on the external edge, and toothed on the sides; and its seeds are triangular, somewhat wrinkled, fully one-third of an inch long, and nearly surrounded with a persistent, shining, brownish-purple pericarp, and contain each 4 or 5 cotyledons. This tree naturally inhabits altitudes immediately below the zone of the wild pine or *Pinus sylvestris;* and is exceedingly hardy as a plantation forest-tree in Britain; and will more or less grow in most situations and soils; yet it is very impatient of the sea-breeze, and makes most progress on good, rich, loamy, deep, rather moist land, in glens or at the base of hills or mountains, and does not thrive well or live long on soil which is either poor or shallow, or in a situation which is bleak or lofty. On its native grounds in Germany, it has always a perfectly straight stem, and attains a height of from 50 to 120 feet, and measures from 10 to 20 feet in girth at two yards from the ground, and is eventually cut from the Black Forest into valuable planks and sent in 'floating villages' down the Rhine to Holland; and in favourable situations, under proper management, in Britain, it is both a free-growing and a highly ornamental tree. A plant of it in Woburn Park, a few years ago, when about the age of 110 years, was 110 feet high, and measured 10½ feet in girth at 4 feet from the ground, and contained 375 cubic feet of timber. The common silver fir is of slower growth, in its earlier years, indeed, than some other hardy and favourite trees of its class; but, after about 15 years, it almost always takes the lead of at once the larch, the spruce, and the Scotch pine. It is, also, very subject, and fatally so, to the disease called the American blight, inflicted by a minute insect of the aphis kind; but it seems to contract this disease in consequence of stagnation and corruption of air, and may generally be protected from it by means of wide enough planting, and of free and early pruning. The reputation it has acquired of being a delicate and comparatively tender tree, appears to have arisen entirely from inattention to the conditions of situation and soil and culture which are proper or essential to its habits. Its timber

is comparatively soft and undurable; and is therefore less imported from foreign countries, and less esteemed by carpenters, than that of the Norway spruce. The liquid resin called Strasburg turpentine is obtained from artificial incisions in its bark, and from punctures of small vesicles under the bark; and is collected in large quantities, in some of the central parts of Continental Europe, by persons who have bottles slung round their waist to receive it, and who climb the trees by means of cramp-irons on their shoes to obtain it.—The twisted-branched silver fir, *Picea pectinata tortuosa*, is a curious variety of the common silver fir, with remarkably crooked or twisted branches and branchlets, of a somewhat peculiar appearance, and very suitable for either pinetums or general evergreen quarters or extensive pleasure-grounds.—The variegated-leaved silver fir, *P. p. foliis variegatis*, is a variety of a strictly ornamental kind.

The balm of Gilead fir, or American silver fir, *Picea balsamea*—formerly called *Pinus balsamea* and *Abies balsamea*—is a native of the northern provinces of North America, and was introduced to Britain toward the close of the 17th century. It is a very beautiful tree, and has an upright habit and a medium size, and has more aspiring branches and a narrower pyramidal head than the common silver fir. Its branches are horizontal; its stem-bark has in general a profusion of small elevated vesicles, which contain a clear limpid resin; its leaves are shorter, narrower, of a lighter colour, and less marked with silveriness below than those of the common silver fir, and are very closely set on the branches, and constitute in the aggregate a richly ornate foliage, and are so balmy as, when bruised, to emit a very fine terebinthine odour; its buds, for next year's shoots, swell in the autumn, and are turgid and of a fine brown colour and very ornamental during all the winter, and exude an agreeable terebinthaceous fluid of similar fragrance to that of the leaves, but stronger; its male catkins are more persistent and more numerously crowded round the shoots of the preceding season than those of the common silver fir; its cones also have a deeper purple colour, and are more swollen in the middle, and have blunter pointed bracts, and taper to both ends, and are sprinkled over at least one side with white resin; and its seeds are similar in shape to those of the common silver fir, but not more than half the size. This tree naturally occurs, not in masses, but scattered among black spruces, hemlock spruces, and other abietinous species; and inhabits principally cold, moist, comparatively poor, clay and gravel soils on the sides of mountains. But in Britain, it loves a good soil, and requires careful treatment, and, after all, often dies from dropsy or decay or other disease before it attains its twentieth or twenty-fifth year. It is much esteemed as an ornamental tree, both on account of its immediate appearance, and for sake of its pleasant fragrance. Its timber is soft, light, and inferior even to that of the common silver fir. The liquid resin popularly called Canada balsam is obtained from it by piercing its bark and puncturing its vesicles; and this was formerly supposed to be very similar to the balm of Gilead, yielded by the oriental, terebinthaceous tree, *Balsamodendron Gileadense*, and hence gave occasion to the name of balm of Gilead fir. See the articles Canada Balsam and Balsamodendron.—A variety of this species, *P. b. longifolia*, differs from the normal plant in having longer leaves and less horizontal or more upright branches.

Fraser's fir, or the double balsam silver fir, *Picea Fraseri*, is a native of Pennsylvania and Carolina, and was introduced to Britain in 1811. It has a dwarfy bushy habit, and seldom attains a height of more than about 12 feet. Its leaves are crowded, straight, flattened, rather regularly pectinated, of a somewhat lightish green colour, and silvery below; its male catkins come out at the extremity of the branches, and are compact, and somewhat oblong, and about half the length of the leaves; its cones are sessile, of a dark brownish colour, about 1½ inch long, and regularly diminishing in diameter from the middle to the two blunt ends; and its seeds are short and of a dark shining purple colour. This plant is hardy and free-growing, and serves well for shrubberies and pleasure grounds. It loves a soil of sandy loam, and may be readily propagated from seeds.

The yew-leaved silver fir, *Picea taxifolia*, is a native of North America, and was introduced to Britain in 1823. It has a pyramidal form, and attains a comparatively good size. Its branches are stiff and nearly horizontal; its bark is rather smooth; and its leaves are thickly pectinate, broad, rounded or notched at the end, of a dark colour, and about an inch or less in length. This species has some resemblance to Fraser's fir, but its bark and young buds are much darker in colour, and its leaves have sometimes a more waved form, and are generally somewhat more silvery below.

Webb's silver fir, or the remarkable silver fir, or the purple-coned Himmalayan silver fir, *Picea Webbiana*, is a native of lofty altitudes in Nepaul, and was introduced to Britain in 1822. It has a similar form and appearance to the common silver fir; but its branches are thicker,—its leaves are larger and broader, solitary and erect,—and its seeds are smaller in size and more elongated and sharp-pointed in form. "This tree," says Captain Webb, by whom it was discovered, "attains a height of 80 or 90 feet, with a diameter of the stem near the ground of 3 or 4 feet. The cone is produced on the extremity of the shoots; the leaves are about one inch long, of a beautiful light green, having a white stripe on the centre. The wood is used for planes, and even equals, in the texture of its grain and in odour, the Bermudas cedar. The fruit is said to yield at full

growth an indigo or purple pigment by expression. The silvery hue of its bark, the beautiful contrast of the leaves, with the rich purple of the cone, glittering with globules of transparent resin, produce in combination one of the most striking objects which can well be imagined, and entitle it to precedence for ornamental purposes."

The noble or large-bracted silver fir, *Picea nobilis*, is a native of the north-west coast of North America, and was introduced to Britain in 1827. It attains a comparatively great size, and promises to be a valuable timber tree for British plantations. Its bark has a somewhat purplish brown colour; its leaves grow chiefly from the sides of the branchlets, and curve upward in a sort of sickle form, and are narrow toward the base, plain on the upper side, furrowed down the middle of one side, prominently ribbed down the middle of the opposite side, acute in the point, of a lightish green colour, silvery on each side of the rib, and about an inch in length; its cones are sessile, solitary, erect, cylindrical, 6 or 7 inches long, and from 2 to 2½ inches in diameter, and grow on the upper sides of the branches; and its seeds are about as large as those of the common silver fir, but lighter in colour, and more pointed in form.

Douglas's silver fir, *Picea Douglasi*, is also a native of the north-west coast of North America, and was introduced to Britain in 1827. It is hardy enough for our climate, and generally takes on two growths in the season. It attains a considerably greater height than the common silver fir, and has a pyramidal outline. Its branches grow in regular whorls, and are at first rather aspiring, and afterwards horizontal, and slightly pendant; its bark is dark-coloured, and often has a profuse sprinkling of small, elevated, resinous vesicles, similar to those of the balm of Gilead fir; its leaves are very loosely pectinate, narrow, straight, rather acutely pointed, from ¾ of an inch to nearly 1½ inch long, and of a light or vivid green colour; its cones greatly resemble those of the cedar of Lebanon, and are 5 or 6 inches long; and its seeds are about the same size as those of the common silver fir, but more oblong, and have thin, broad, shining, pale brownish wings.

SILVER-WEED, — botanically *Argyreia*. A genus of ornamental, tropical, evergreen, twining plants, of the bindweed family. Eight or nine species, principally from 10 to 30 feet high, and carrying either white, pink, purple, or crimson flowers, have been introduced to the hothouses of Britain; and several more are known. Most formerly belonged to the genus lettsomia. Both the popular and the botanical names allude to the silvery texture of the leaves. All the species are propagated from cuttings; and most love a rich mould soil.—Silver-weed is also a popular and common name of the abundant British weed *Potentilla anserina*. See the article Potentilla.

SILYBUM. A small genus of herbaceous plants, of the thistle division of the composite order. The Virgin Mary's species, or welted thistle, or curled thistle, *Silybum marianum*, called by Linnæus *Carduus marianus*, is a biennial weed of the banks and similar situations of Britain. It has commonly a height of about 4 or 5 feet, and carries purple flowers in July. See the article Thistle.

SIMABA. A genus of tropical ligneous plants, of the simaruba family. The Orinoco species, *S. orinocensis*, was introduced to Britain about 30 years ago from Orinoco. It is an evergreen, white-flowered shrub, of about 10 feet in height; and possesses, in a comparatively high degree, some valuable medicinal properties, and is at the same time decidedly ornamental. It loves a soil of loamy peat, and may be propagated from cuttings. Another species has been introduced from Guiana; and 5 or 6 other species are known.

SIMARUBA. A small genus of tropical ligneous plants, constituting the type of the natural order Simarubeæ or Simarubaceæ. The known species of this order do not amount to twenty, and occur principally in tropical America, and are all trees or shrubs with pinnated leaves, a milky juice, and an intensely bitter bark. Several possess eminently excellent tonic properties; and all seem to be more or less medicinal. Only 5 or 6 species, belonging to the three genera simaruba, simaba, and quassia, have been introduced to British hothouses; and two of these are true simarubas, and furnish almost all the quassia-bark and quassia-wood of commerce. The flowers have a quinate calyx and a five-petalled corolla; and the fruit comprises five distant, bivalve berries, seated in a fleshy receptacle.

The officinal simaruba, *S. officinalis*, called by Linnæus *Quassia simaruba*, is a native of the West Indies and of the tropical parts of Continental America, and was introduced about 60 years ago to the hothouses of Britain. It is called, in Jamaica, the mountain damson. Its stem attains the height of a tall shrub or low tree; its branches are alternate; its bark is smooth and grey, variegated with yellow spots; its leaves are pinnate, and comprise each from two to nine smooth, deep green, acute-elliptic leaflets; its flowers have lanceolate petals, of a yellowish white colour; and its berries are ovate, smooth, and black. The bark of the root is imported by druggists, from the West Indies, in long pieces of a few inches in breadth; and is used, to a considerable extent, in British medicine, under the name of quassia bark. It is rough, scaly, warty, of a yellow colour within, inodorous, and very bitter; and it contains malic acid, gallic acid, malate of lime, oxalate of lime, acetate of potash, oxide of iron, alumina, a volatile oil, an ammoniacal salt, and a peculiar bitter principle called quassine. It has powerfully tonic properties; and is administered

in cases of dyspepsy, dysentery, obstinate diarrhœa, and intermittent fever.

The lofty simaruba, *S. excelsa*, called by the old botanists *Quassia excelsa*, is a native of Surinam, Jamaica, and the Caribbean Islands, and was introduced to the botanical collections of Britain in 1818. It is called in some of its native districts the bitter ash. It is a tall and beautiful evergreen tree. Its stem is straight, tapering, and smooth, and naturally rises to the height of from 40 to 100 feet, and has, in many instances, a girth of about 10 feet near the base ; its bark is grey and smooth ; its leaves are pinnate, and have reddish ribs, and comprise each from 5 to 8 pairs of opposite, oblong, pointed leaflets, and a terminating odd one ; its flowers come out in clusters, and are small and of a yellowish green colour ; and its berries are black, spherical, and about the size of pease. The wood of this species is imported in billets, and chipped or rasped by the druggists ; it is inodorous, and has a pale yellow colour, and an intensely bitter taste ; it contains much of the peculiar principle called quassine ; and it possesses similar tonic properties, and is used for similar medicinal purposes as the root-bark of the officinal species.

SINAPIA. See Mustard.

SINGLE-SEEDED CUCUMBER. See Sicyos.

SINGLING OF TURNIPS. See Turnip.

SINNINGIA. A genus of ornamental tropical plants, of the gesneria family. Six species, all small evergreen undershrubs, varying in height from 10 to 20 inches, and blooming for the most part in summer, and having flowers with some predominance of either yellow or white in their colours, have been introduced to the hothouses of Britain ; and all love a soil of peaty loam, and may be propagated from cuttings.

SIPHOCAMPYLOS. A genus of ornamental, tropical American plants, of the lobelia family. It first became known in Britain in 1835 ; and it very soon and generally acquired the fame of an eminently beautiful genus. Several of its species are very nearly allied to the true lobelias ; but others possess very distinct characters of their own, and are remarkable for both the elegance of their habit and the brilliance of their flowers.—The revolute species, *S. revolutus*, was introduced in 1839. Its stem is erect, cylindrical, villous, green, and sparingly branched, and speedily attains a height of about 5 feet ; its branches are zigzag ; its leaves are stalked, alternate, rigid, wrinkled, spreading, villous, cordate-ovate, acuminate, reflexed in the edge, simply dentate, and the upper ones revolute in the apex ; and its flowers come out on solitary, erect, axillary footstalks, and have a green, villous, turbinately-hemispherical calyx, and a purplish-red, large, tubular corolla, five times as long as the calyx.—The latana-leaved species, *S. latanifolius*, was introduced from Caraccas in 1844. Its stem is erect and shrubby ; its leaves are stalked, oval, and rather large ; and its flowers come out in terminal, many-flowered racemes, and have long, tubular, deep-crimson-coloured corollas, with five-parted, reflex, and interiorly pale pink-coloured limb, and bloom in spring. This plant has a good appearance, but is of rather weak growth.—The scarlet-flowered species, *S. coccineus*, was introduced from the Organ Mountains of Brazil about 5 or 6 years ago, and has been prominently exhibited at public shows, and greatly admired. Its stems are numerous, and have aggregately a tufty appearance, and are shrubby at the base and comparatively succulent above ; its leaves are alternate, broadly oval, doubly serrated, and glabrous ; and its flowers come out singly from the axils of several of the leaves toward the top of the stems, and are large, of a bright scarlet colour, two inches or more in length, and somewhat similar to the flowers of the tubular scarlet salvias, and continue a long time in bloom. This plant requires a moderate rich loamy soil, in well-drained, moderately-sized pots ; and must be allowed as entire repose as possible during winter.

SIPHONIA. A small genus of ornamental, tropical, evergreen shrubs, of the spurge family. The caoutchouc species, *S. cahuchu*, was introduced to the botanical collections of Britain, about 25 years ago, from Guiana. It has a height of about 6 feet, and thrives best in a soil of sandy loam, and may be propagated from cuttings. It yields some of the caoutchouc of commerce.

SISKIN,—scientifically *Carduelis Spinus*. A British song-bird of the finch group of Passerinæ. It is sometimes called the aberdivine ; and is somewhat liable to be confounded with some of the most nearly allied species of Fringillidæ. Its total length is $4\frac{5}{8}$ inches ; its bill is somewhat like that of the goldfinch ; its body is olive brown above and yellow below ; and its wings and tail are streaked with black. It arrives in Britain, from the north, in flocks, either alone, or more frequently in company with linnets and redpoles, in autumn, and remains in this country till April. It feeds on the seeds of the larch, the birch, and the alder.

SISON. See Honeywort.

SISYMBRIUM. See Hedge-Mustard.

SISYRINCHIUM. A genus of ornamental, exotic, herbaceous, evergreen plants, of the iris order. Upwards of 20 species have been introduced to Britain, from various parts of North America, between California and Brazil ; and some suit the open border, some the frame, some the greenhouse, and some the stove. All are more or less beautiful ; and the majority have a height somewhat between 3 and 25 inches, and carry either white, blue, or yellow flowers, and are most readily propagated by division. Three of the finest are the large-flowered, *S. grandiflorum*, hardy, about a hand high, carrying dark purple flowers in May and June ; Cumming's, *S. Cummingii*, a frame plant, about a foot high, carrying cream-coloured flowers from June till August ;

and the slightly hairy, *S. hirtellum*, a frame plant, 8 or 10 inches high, carrying white flowers in June and July. The name sisyrinchium signifies swine's snout, and is supposed to have arisen from the fondness of hogs for the roots of the species to which the name was originally applied, —not a plant of this genus, however, but an iris.

SITFAST. An indurated tumour on the back of a horse, occasioned by the pressure of the saddle. It generally requires to be dissected out, and should be done so gently and carefully; and if the skin of the part be horny, it also must be removed. To detach the tumour slowly by rubbing with mercurial ointment or by blistering would involve more pain and trouble, and at the same time prove less efficient, than to dissect it out; and to tear it simply off with pincers would be brutal. The name sitfast is a barbarism, yet is not undescriptive.

SITONA. See Weevil.

SIUM. See Water-Parsnip and Honeywort.

SIZE. See Glue.

SIZZING. Yeast or any similar ferment.

SKEEL. A broad flat milk dish; also a large milking pail with two vertical handles, formed by two opposite projecting staves.

SKEP. A bee-hive; also, a coarse, round, farm basket.

SKID. A chain with which the wheel of a waggon is so fastened as to prevent it from revolving on the descent of a declivity. See the article Drag.

SKILLING. A bay of a barn.

SKIM. See Plough.

SKIN. The natural covering of the body of animals. It defines the form of the body, protects it from injury, modifies the action of the surrounding elements, indicates sensation from without to the interior parts, and comprises an inconceivably minute and complex texture of organisms for the offices of touch, of exudation, of absorption, and of many of the parts or concomitants or dependencies of the highest functions of animal life. Volumes might be written to describe the wonders of the skin, and to explain how mightily and countlessly they display the wisdom and beneficence of the Creator. But we can afford, within our limited space, to do no more than give a general indication of the skin's structure,—and even this with reference only to the constitution and health of the domesticated animals.

Three successive layers constitute the skin,—first, the cuticle, epidermis, insensible skin, or scarf skin,—second, the rete mucosum, or corpus mucosum,—and third, the cutis, corium, sensible skin or true skin; and two grand provisions exist everywhere in connexion with it as concomitant systems,—first, the hair, rising up from the cutis through the cuticle to a growth on the exterior, —and second, the panniculus carnosus, spreading beneath a great portion of the cutis of quadrupeds, and possessing more power and extent in the thin-skinned and thin-haired than in the thick-skinned and thick-haired.

The cuticle and the hair have already been sufficiently noticed in the articles Cuticle and Hair. The rete mucosum is a thin, soft substance, of mucous or mucilaginous consistence, extending between the cuticle and the cutis, and comprising the intricate ramification of minute nerves and blood-vessels which connects the influences and agencies on the exterior of the body with the capacities and functions of the interior. Many of the vessels in its net-work are so minute that no magnifying power hitherto used can enable the eye to trace them to their source; and part of them are said to contain a sluggish, stagnant fluid, which constitutes the colouring matter of the skin; while others bring up from within, and pour out through the cuticle, the fluid matter of either exhalation or exudation. See the article Perspiration. "The minute vessels which supply the exhalants cannot by any physical means be traced to their insertion into the blood-vessels; and the physiology of this interesting portion of the animal economy is still in a very imperfect state; nevertheless, that these ducts are connected with the blood-vessels is proved by their becoming filled with blood on friction of the skin, or by any bodily exertion which creates perspiration, or, in man, by certain actions of the mind, such as modesty, shame, and anger." The rete mucosum of a white man is white, of a mulatto tawny, and of a negro black; and that of a white-haired horse is white, of a brown-haired one brown, and of a black-haired one black,— the rete mucosum of both man and beast being, in every instance, the seat of the colour or complexion of the body.

The cutis or true skin is a strong, elastic, fibrous, exceedingly vascular, highly sensitive, intricately organized membrane. "It appears," says Mr. Percivall, speaking of it particularly as it exists in the horse, "to consist of a dense substratum of cellular tissue, with which are interwoven fibres of a ligamentous nature, in such a manner that innumerable areolæ, like the meshes of a net, are formed in it. These areolæ open, through correspondent pores in the cuticle, upon the external surface, and are for the purpose of transmitting thither blood-vessels and absorbents, giving passage to the hair, and lodging the various secretory organs of the skin." It binds together the different parts of the horse's or ox's or other animal's frame; and is the substance which, when removed from the body and manipulated by the tanner and the currier, constitutes leather. See the articles Hide and Leather. It is thickest in the most exposed parts of the body, and thinnest in the least exposed; and it clings tightly to parts which have little or no local motion, and hangs loosely or even in folds on parts which have much local motion. "Its outer surface is garnished with numerous papillæ, which are small eminences extremely sen-

sible, lying under the cuticle, and received into its depressions; and wherever the skin is most sensible, these papillæ are found most numerous and extensive. The cutis, like the cuticle, is perforated by numerous openings, which are the exhalent and inhalent orifices,—and by the ducts of its sebaceous glands, which are in greater plenty in some parts than in others, as in the nose and ears, as well as in parts subjected to friction."

The panniculus carnosus or fleshy panicle is a remarkable muscular expansion, extending beneath a great part of the skin of horses and other quadrupeds, and serving, in many respects, as a compensation for the want of hands. "It enables them to corrugate the skin, and thus to shake off dust, prevent the attack of noxious insects, and perform other purposes necessary for their ease and convenience. In different tribes, it has different attachments; and consequently its action and powers become varied also. In the horse and all the mammalia with short hair, it is, by the extent of its attachments, capable of very powerful and diffused operations. Its centres are usually muscular, and its terminal attachments often aponeurotic, ending sometimes into other muscles or their fascias; by which, as either or any of these become the fixed point or points, the action of the whole may be changed at pleasure either partially or totally." It is everywhere very plentifully supplied with nerves, and is traversed by some which ascend through it to the skin; it is likewise well supplied with blood-vessels from the intercostals and neighbouring parts; and it has therefore much irritability and comparatively great vital power,—and may be supposed to assist the skin in bracing the portion of the frame which it covers, and probably to aid also in strengthening the muscles which are situated below.

"The skin, while the animal is alive," says Youatt, with special reference to the horse, "is one of the most elastic bodies with which we are acquainted. It not only perfectly adapts itself to the slow growth or decrease of the body, and appears equally to fit, whether the horse is in the plumpest condition or reduced to a skeleton; but, when a portion of it is distended to an extraordinary degree, in the most powerful action of the muscles, it, in a moment, again contracts to its usual dimensions. It is principally indebted for this elasticity to almost innumerable minute glands which pour out an oily fluid that softens and supples it. When the horse is in health, and every organ discharges its proper functions, a certain quantity of this unctuous matter is spread over the surface of the skin, and is contained in all the pores that penetrate its substance, and the skin becomes pliable, easily raised from the texture beneath, and presenting that peculiar yielding softness and elasticity which experience has proved to be the best proofs of the condition, or, in other words, the general health of the animal. Then, too, from the oiliness and softness of the skin, the hair lies in its natural and proper direction, and is smooth and glossy. When the system is deranged, and especially the digestive system, and the vessels concerned in the nourishment of the animal feebly act, those of the skin evidently sympathize. This oily secretion is no more thrown out; the skin loses its pliancy; it seems to cling to the animal, and we have that peculiar appearance which we call hide-bound. This, however, requires attentive consideration. We observe a horse in the summer. We find him with a thin smooth glossy coat, and his extremities clean and free almost from a single rough or misplaced hair. We meet with him again towards the winter, when the thermometer has fallen almost or quite to the freezing point, and we scarcely recognise him in his thick, rough, coarse, colourless coat, and his legs enveloped in long shaggy hair. The health of the horse is, to a certain degree, deranged. He is dull, languid, easily fatigued. He will break into a sweat with the slightest exertion, and it is almost impossible thoroughly to dry him. He may perhaps feed as well as usual, although that will not generally be the case, but he is not equal to the demands which we are compelled to make upon him. This process goes on for an uncertain time, depending on the constitution of the animal, until nature has effected a change, and then he once more rallies. But a great alteration has taken place in him—the hair has lost its soft and glossy character, and is become dry and staring. The skin ceases to secrete that peculiar unctuous matter which kept it soft and flexible, and becomes dry and scaly; and the exhalents on the surface, having become relaxed, are frequently pouring out a profuse perspiration, without any apparent adequate cause for it. So passes the approach to winter, and the owner complains sadly of the appearance of his steed, and, according to the old custom, gives him plenty of cordial balls,—perhaps too many of them,—on the whole not being unserviceable at this critical period, yet not productive of a great deal of good. At length the animal rallies of himself, and although not so strong and full of spirits as he ought to be, is hardier and more lively than he was, and able to struggle with the cold of the coming winter. What a desideratum in the management of the horse would be a course of treatment that would render all this unnecessary? This desideratum has been found—a free escape of perspiration, a moist and softened state of the skin, an evident increase of health and capability of enduring fatigue, and working on shorter supply of food than he could before. This is said to be performed by the clipping and singeing systems."

SKIRRET, — botanically *Sium Sisarum*. A hardy, tuberous-rooted, culinary plant, of the umbelliferous order. It is a native of China,

and was introduced to Britain about the middle of the 16th century. The root comprises several fleshy or tuberous fibres, as large as a man's little finger, which join together in one head; the stalk is about a foot high; the lower leaves are pinnate, each comprising two or three pairs of oblong leaflets, and a terminating odd one; the flowers grow in an umbel on the top of the stem, and are white, and bloom in July and August; and the seeds are striated like those of parsley, and ripen in autumn. This plant is raised either from seeds sown in drills in spring, with a subsequent thinning out of the plantlets to distances of 6 inches, or from side offsets of the old roots, planted in spring and in autumn. The roots were formerly mentioned in old dispensatories as medicinal; and were long esteemed wholesome, nourishing, and agreeably culinary, and were boiled and eaten whole in summer, autumn, and winter; but they are now used scarcely ever for medicine, and very seldom even for food; for they are flatulent and very sweet and unpleasant to many palates.

SKOVES. Bundles of corn or unbound sheaves.

SKULL. See HEAD.

SKULLCAP,—botanically *Scutellaria*. A genus of ornamental herbaceous plants, of the labiate order. Two species grow wild in Britain, about 30 have been introduced from other countries, and a good many more are known. All the introduced species, except two evergreens from Australia and Havannah, are hardy, annual-stemmed perennials; most have a height of between 6 and 25 inches; the majority have blue-coloured flowers; and seven produce their flowers solitarily from the axils, two spicately and racemosely from the axils, two compoundly and racemosely from the summit, and the rest simply and racemosely from the summit. The name scutellaria signifies 'a little saucer,' and alludes to the form of the calyx.

The common or small-capped skullcap, *S. galericulata*, inhabits the ditches, the reedy river margins, and other watery situations in many parts of Britain. Its root is creeping; its herbage has a deep green colour, often tinged with violet, and is more or less downy; its stem is erect, leafy or branched, and from 10 to 20 inches high; its leaves stand on very short footstalks, and are heart-shaped at the base, lanceolate, crenate, rugged, somewhat wrinkled, and upwards of an inch long; and its flowers are axillary, solitary, almost sessile, drooping, about an inch long, scentless, variegatedly blue throughout with streaks of white on the lip, and bloom from June till September.

The lesser skullcap, *S. minor*, inhabits moist hedges, and similar situations in Britain. Its stem is more branched than that of the common species, but only about 6 inches high; its leaves are broader than those of the common species, and almost of a hastate form; and its flowers grow in the same manner as those of the common species, but are smaller, and have a delicate pink colour almost inclining to blue, and bloom in July and August.

Some of the most handsome of the introduced species are *S. hastifolia*, 6 inches high, with axillary, solitary, purple flowers, from Germany,—*S. lateriflora*, a foot high, with racemose, axillary, blue flowers, from North America,—*S. alpina*, 9 or 10 inches high, with simply racemose, terminal, blue and white flowers, from Hungary, but comprising blood-red-flowered and variegated-flowered varieties from other countries,—*S. altissima*, 12 or 15 inches high, with simply racemose, terminal, dark purple flowers from the Levant,—*S. peregrina*, 2 feet high, with simply racemose, terminal, violet flowers, from Italy,—and *S. pilosa*, a foot high, with compoundly racemose, terminal, blue flowers, from North America. These species and many others are well suited to adorn the front of the open border; and they thrive in any common garden soil or in a peaty loam, and may be propagated either from seeds or by division.

SKY-LARK. See LARK.

SLAB. The outside plank of a log or boll of timber when sawn into boards; also a flat thin piece of marble or of other compact stone.

SLATE. A thin slab of any kind of rock of a compact texture and laminated structure, which splits into desirable thicknesses for the purpose of covering roofs. All the stratified rocks, whether primitive or transition, secondary or tertiary, which admit of being split, are comprehensively called slate rocks,—and they may be very variously classified according to the several theories of science and the several designs of economy; but the argillaceous schists, or those rocks which furnish the best roofing slates of commerce, such as the blue clay schists of Wales and of the Western Highlands and Islands of Scotland, take the name of slate rocks par excellence.

The transition slate-rocks form the substrata and even the soil of a large portion of the well-farmed districts of Scotland, as well as of some most interesting parts of Ireland and of Wales; and they demand some special study on the part of farmers, on account of the difference of their constitution from that of the other prevailing rocks of the arable surfaces of Britain, and on account too of wide differences of constitution among themselves. They need to be well understood, especially, in reference to the paucity and the very variable proportions of their lime. Professor Johnston, speaking of specimens that were gathered from the great greywacke formation of the south of Scotland, and subjected to analytical examination in his laboratory, says:—"Many of them were traversed by white hair-like streaks of carbonate of lime, and nearly all of them exhibited a slight effervescence when treated with acid, showing that they contained traces of lime in the state of carbonate. The results of the analyses of seven varieties were as follows:—

	1.	2.	3.	4.	5.	6.	7.
Lime in state of carbonate, per cent.,	7·19	0·26	1·98	0·25	0·22	....	0 19
Lime in state of silicate,	0·24	0·62	0·30	1·09	0·43	0·50	....
Total lime per cent.,	7·43	0 88	2·28	1·34	0·65	0 50	0·19

The proportion of lime, therefore, in the different beds of this formation is small. In general, therefore, the soils formed from them will be deficient in lime; and hence the reason why in practice it has been found that the addition of lime is an almost necessary preliminary to any successful and permanent improvement of the surface where these soils prevail. At the same time, it will be seen by the composition of No. 1 that some beds contain what may be called a large quantity of lime, and will therefore form soils that are of a richer character. The waters also that percolate through them, or the springs that rise from among them, will contain a considerable quantity of lime, and they may both sweeten the natural herbage, and when they collect in lakes and marshy places, may yield lime enough to admit of the gradual deposition of beds of marl.—The old red sandstone slates also vary in the proportion of lime they contain. Such a slate from Fotheringham estate in Forfarshire gave—

Lime in the state of carbonate,	0·39 per cent.
Do. do. silicate,	0·87 "
Total lime,	1·09 per cent.

The known fertility of certain soils belonging to the old red sandstone formation does not depend merely on the proportion of lime they contain; yet, in the less fertile parts of this formation, the per centage of lime contained in the rocks exercises a material influence on the agricultural capability of the soils which rest upon or are formed from them."

SLATING. In England where slates are very generally used for covering the best buildings, they are split and cut at the quarry into square plates, and are sold and distinguished by the following singular names, depending on their quality and size.

Doubles, are	1 ft. 2 inches	by 0	6
Ladies,	1 ,, 3 ,,	by 0	8
Countess's,	1 ,, 10 ,,	by 0	11
Duchess's	2 ,, 2 ,,	by 1	3
Queen's (also called Rags),	3 ,, 3 ,,	by 2	3
Imperials and patent,	2 ,, 8 ,,	by 2	2

They are sold by the 100. The quantity necessary to cover a square of roofing of the first four kinds will weigh from 6 to 7 cwt. The large slates being also thicker will weigh from 7 cwt. to a ton. The word *patent* applies to the mode of fixing and not to the slate. Slates, from their being thin and brittle, require a certain degree of skill in the cutting, making the nail holes, and laying, so as to prevent waste, and on this account their use is considered a separate branch of business, and is performed by the slater. Iron nails are used to fix shingles, and endure as long as the shingles will last; but as good slates may be considered everlasting (unless broken or injured by accident), they ought to be fixed with copper nails, that do not rust away. Roofs are occasionally covered with sheet lead, copper, or zinc, in all which cases they must be covered with planed boarding, and the long joints in the metal should be vertical, and not soldered, but so constructed as to admit of expansion and contraction.

SLAUGHTERING. See MEAT.

SLEDGE. A slide-car or drag-cart. See the article CART. An improved sledge, for carrying turf, hay, or other heavy commodities down slopes which are impracticable for any wheeled vehicle, may be made with iron-shod ash or elm soles, and ash rail body of 4½ feet square or so at bottom, and drawn by chains of 7 feet in length, and bar-iron stilts of 5 feet in length, aided by a small friction wheel. A figure and plan and details of such a machine are given by Mr. Cook of Yetholm in the 8th volume of the Highland Society's Transactions.

SLENDER-BODIES. See GEOMETERS.

SLINKING. See ABORTION.

SLEEP. The phenomena of sleep bear an immediate relation to the most general laws of Nature, and form an important illustration of the fact, that the periodical motions of the animal economy are in direct correspondence with the movements of our planetary system, and especially with our situation relative to that sun which regulates the periods of the day and year. "All our wants reappear," says Cabanis, "and all our functions execute themselves, in fixed and isochronous periods. The duration of the functions is the same in each period; the same appetites or the same wants have the hours marked for their return; and it commonly happens, when these wants are not immediately satisfied, they diminish and disappear for a certain time, only to return again with the greater force and importunity at the next succeeding period, which ought to produce a return of the impression. This character of periodicity is particularly remarkable in the returns and duration of sleep, which commonly reappears during each astronomical day at the same hour; continues nearly for the same period of time; and according as it is regular in its periods, slumber is the more easy, while the repose which follows is the more salutary and refreshing."

There are two principal states of vital activity, of which all animals partake in different degrees. When the vital excitement exists to its full extent, the animal is said to be *awake;* when the functions of life are suspended, either wholly or partially, it is said to be *asleep.* From this waking state, when life exists in all its plenitude, there may be many degrees of its diminution, called *reverie*, *delirium*, *dreaming*, *sleep*, *torpor*, *stupor*, *asphyxia*, *lethargy*, according to their intensity, of which states the last is but one degree removed from absolute death.

The principal occasions on which these states of vital repose naturally present themselves to our observation are, 1st, When the body and

mind of an animal languish either from the return of their period of natural repose, or through excessive exertion. 2d, When the cold of winter, or perhaps also the heat of summer, acting on special constitutions, suspends the animal functions of life either partially or entirely. The former phenomenon appears daily, while the latter is of annual recurrence.

The first of these occasions, or sleep properly so called, differs from death, with which it has often been compared, in the circumstance that all the involuntary functions of life continue their action uninterruptedly. It may be recollected that animals have two kinds of vital functions; the one vegetative and internal, which continue, with the exception of generation, to exert themselves during the entire existence of each individual, and the other purely animal, which refer to external objects. The former being essential to their existence, are never suspended; the latter are intermittent in their action. If the heart ceased to propel the blood through the arteries, if the lungs ceased to respire air, if the functions of nutrition and secretion were discontinued, or if they depended upon the mere will of the animal, life would soon become extinct. But all these internal actions are involuntary, and hence it is only the external and purely animal functions of life which can have their periods of action and repose, of waking and sleeping. These latter actions are therefore less essential to life than the former. An animal, when profoundly asleep, is reduced to a state very analogous to that of a plant. Though dormant, he is still a living being, for he continues to perform the functions of nutrition and secretion even more perfectly than when awake; but he is destitute both of sensation and motion, and must awake before he can fully resume these functions peculiar to animals. Thus animals have two states of existence, waking and sleeping, while a plant has only one. The state of the latter may, however, be more or less active, according to the different degrees of heat or light to which it is exposed. There can be no difference with plants between the activity of the internal and external functions, and they always appear to be plunged in a state of repose more or less profound. Many of the lower animals, such as an oyster or a zoophyte, when considered superficially, appear to exist in a continued state of torpor, rather than to possess an active life, because they maintain but few relations to external objects, and hence are commonly considered rather as vegetating than as living, although plants are possessed of life as well as animals, but only in different degrees.

Sleep, in fact, consists in the suspension of the organs of sense and voluntary motion, qualities which chiefly serve to distinguish animals from plants. All the voluntary muscles repose completely, and the sleeping animal maintains no active relations with external objects. The functions belonging to vegetable life continue their existence, but the consciousness of existence is lost. The heart and the lungs continue to act without interruption, while the organs of thought and sensation possess but a temporary action. It is thus precisely those organs which are the most intimately connected with the mind, namely, the organs of thought and sensation, which most require repose, and the human soul, though immortal, when entirely separated from the body, cannot now maintain its consciousness uninterruptedly for twenty-four hours together.

Night, or the absence of light, is favourable to the sleep of all animals not naturally of nocturnal habits. Silence, repose, the absence of noise, and in general every thing which interrupts the relations of the animal with external objects, are favourable to sleep. As long as the purely animal functions continue to be stimulated, they maintain their action, until an excess of action produces a contrary effect. A violent exertion of the body, profound thought, or any powerful sensation, disposes for sleep. Often the fatigue of a single sense brings on the sleep of all the senses, through that intimate connexion maintained among all the parts of the body. The monotonous murmurs of a brook, the howling of a forest, bad music, protracted reading, bad verses, or a long lecture on an uninteresting subject, gradually fatigue the sense of hearing or sight, and lead the vital forces of these organs to seek in sleep for an accession of energy, and the repose of the entire animal functions speedily follows.

The inclination to sleep is announced by a slowness of motion, by languor of the attention and will, and by the gradual stupefaction of the senses. But the different kinds of functions are suspended in a certain order of succession, according to their nature and relative importance. The muscles which move the arms and legs are relaxed and cease to act before those which sustain the head, and the latter before those which support the spine. When the sense of sight is first suspended by the falling of the eyelids, the other senses still maintain their action. The sense of smelling is obliterated before the taste; hearing after smelling; and touch last of all. Even during the most profound sleep, the sense of touch continues to suggest different movements and changes of position, when the long duration of the same posture renders it disagreeable. At length animal exertion is at an end; the muscles, excepting those of circulation and respiration, cease to act; and the body sinks down, obedient to the ever-acting force of gravitation.

These phenomena of sleep are very analogous to that insensibility of particular organs, during our waking moments, when the attention is fully engaged. A profound mathematician, when absorbed in a calculation, neither sees, hears, nor feels; all the functions are asleep except the

organ of thought. Other men, like mere machines moved by habit, perform the same operation a thousand times with their hands, while the thinking principle remains buried in a profound lethargy.

At the precise moment when the mind loses its consciousness, there results a general relaxation of all the muscles. If the body be at rest and in health, this sudden change in its state of obedience to the will is attended with no marked result. But if the body be fatigued, or in an uneasy posture, or if the joints or muscles be painful, this first result of sleep has the effect of removing it entirely. Hence arises the difficulty of sleeping in a sitting posture, or during an attack of gout or rheumatism. The pain which the sudden starting of the muscles occasions is often so great in these diseases, that sleep can only be induced by strong doses of opium or some other narcotic. It also follows from this relaxation of the muscles, that the limbs become bent during sleep, and that a substance grasped firmly in the hand, falls at the instant when consciousness is lost. During sleep the character of the respiration is altered; it becomes less frequent and deeper. The heart also beats more slowly, but the pulse is stronger. The heat of the surrounding air, when imperfectly renewed, tends, however, to increase its movements. The heat of the body is not naturally higher during sleep; on the contrary, a diminished respiration tends to lower the temperature. It usually happens, however, from external circumstances, that there is an apparent rise of temperature, from the body being surrounded by imperfect conductors of heat, and from the circumambient air being but slowly renewed.

As the stomach is a muscular organ, and as the passage of the food through the pylorus depends upon the rapidity with which the almost insensible contractions of the stomach are performed, it follows that sleep retards digestion, while, at the same time, it renders it more complete. This slowness of digestion is further increased by the state of rest in which the body remains, as nothing tends more to excite a rapid digestion than the gentle motion of the limbs, or of the entire body. The same phenomena take place in the intestines, where the aliments remain almost inert in the several portions of the alimentary canal. However, the slowness of this movement favours the formation of chyle, and renders its absorption more complete.

Absorption is very active during sleep, and the danger of slumbering in noxious air hence becomes very great. Travellers are usually advised to avoid sleeping in marshy situations, such as the Pontine marshes of Italy, especially in the warm season of the year. Perspiration also is performed more easily, because the pores remain open during the state of muscular relaxation. "Une nutrition plus efficace, la réparation graduelle des forces qui en résulte, et aussi la réplétion de la vessie, toutes ces choses réveillent en nous, durant le sommeil, des idées de jouissance et des souvenirs de volupté." As all the senses do not fall asleep at the same time, so they differ in the order in which they awake. Taste and smell commonly resume their functions last of all. The sense of sight is roused with greater difficulty than that of hearing. An unexpected noise will often awaken a somnambulist from his lethargy, upon whom the strongest rays of light will have had no previous effect, although his eyes continue open. Touch, as it was the last sense to become dormant, so it appears to be the most easily roused. The same person who cannot be awakened by very loud noises, will rise instantly on being gently tickled on the soles of the feet. Often the mere approach of the respiration of another will be sufficient to rouse the soundest sleeper.

The positions which the mammalia assume during sleep are very various. The young animal sleeps with its limbs gathered together, in a posture most resembling that of the fœtus in the womb. This situation is very favourable to the renewal of the animal forces, by permitting the relaxation of all the articulations, and in preserving the heat of the more sensitive parts. For the latter reason, the dog and cat sleep with their bodies formed into a circle. Some mammalia sleep in the open air, while others retire to caves and sheltered places. Many repose without any covering, while others prepare a bed of some imperfectly-conducting substance, to preserve the temperature of their bodies, which would otherwise fall during sleep below the natural standard. It is usually on the right side that man reposes. This posture favours the action both of the heart and stomach, as the vibrations of the former would reverberate through the body from the reaction of the substance upon which it reposes, and the latter would be compressed by the weight of the liver. After sleep, all the organs, being refreshed, repaired, and completely nourished, acquire a greater size; thus man and other animals which commonly hold the spine more or less erect, are taller in the morning than in the evening after the fatigues of the day.

Sleep is not always profound; some of the animal functions continue to act; ideas succeed each other, and the animal is said to dream. The power of dreaming is falsely ascribed to man alone; other mammalia dream likewise, because they are capable of thought, and possess a certain degree of intelligence. Sometimes the dog is observed to howl, struggle, and perspire copiously. Moving his tail and limbs rapidly, he pursues the hare in imagination, and, on the point of seizing it, closes his teeth and lips as if in the act of dyeing them in blood. Some birds are also known to dream, as the parrots. Those animals which are most easily excited dream more frequently than the others; thus the horse

is more liable to dream than the bull. According to Chabert, this phenomenon among cattle is only observed in the bull, the ram, or in cows which are suckling.

It is possible to protract the usual period of sleep by an unusual excitement; but if the stimulus be long continued its effect goes off, and then nothing can prevent sleep as long as the health continues good. In fact, sleep, once in the twenty-four hours, is as essential to the existence of the mammalia as the momentary respiration of fresh air. The most unfavourable conditions for sleep cannot prevent its approach. Coachmen slumber on their coaches and couriers on their horses, while soldiers fall asleep on the field of battle, amidst all the noise of artillery and the tumult of war. During the retreat of Sir John Moore, several of the British soldiers were reported to have fallen asleep upon the march, and yet they continued walking onwards. The most violent passions and excitement of the mind cannot preserve even powerful minds from sleep; thus Alexander the Great slept on the field of Arbela, and Napoleon upon that of Austerlitz. Even stripes and torture cannot keep off sleep, as criminals have been known to slumber on the rack. Noises which serve at first to drive away sleep, soon become indispensable to its existence; thus a stage-coach stopping to change horses, wakes all the passengers. The proprietor of an iron forge, who slept close to the din of hammers, forges, and blast furnaces, would awake if there was any interruption to them during the night; and a sick miller, who had his mill stopped on this account, passed sleepless nights until the mill resumed its usual noise. Homer, in the Iliad, elegantly represents sleep as overcoming all men, and even the gods, excepting Jupiter alone.

The length of time passed in sleep is not the same for all men; it varies in different individuals and at different ages; but nothing can be determined from the time past in sleep, relative to the strength or energy of the functions of the body or mind. From six to nine hours is the average proportion, yet the Roman Emperor Caligula slept only three hours, Frederic of Prussia and Dr. John Hunter consumed only four or five hours in repose, while the great Scipio slept during eight. A rich and lazy citizen will slumber from ten to twelve hours daily. It is during infancy that sleep is longest and most profound. Women also sleep longer than men, and young men longer than old. Sleep is driven away during convalescence after a long sickness, by a continued fasting, and the abuse of coffee. The sleepless nights of old age are almost proverbial. It would appear that carnivorous animals sleep in general longer than the herbivorous, as the superior activity of the muscles and senses of the former seem more especially to require repair. Satiated with their prey, they are obliged to seek repose to digest those very substantial matters which compose their aliment.

In general, it may be stated, that during sleep the internal functions predominate over those relating to the exterior of the body. Every thing which tends to interrupt the relaxations of the external with surrounding objects serves to induce sleep. On the contrary, the existence of external stimuli tend to expel it, until at length they lose their effect by long-continued exercise. From this it ought to follow that excessive cold, which benumbs the external powers, ought to occasion sleep. When exposed to the action of a low temperature, animals experience an irresistible desire to sleep which soon terminates in death. Of this there are frequent examples in the inhospitable climates of the north, Siberia, Lapland, and Kamtschatka, or on the tops of high mountains, as the glaciers of Switzerland. Dr. Solander and party nearly lost their lives from this cause among the hills of Terra del Fuego. Surprised by an excessive cold, he was with difficulty prevented by his companions from yielding to this impulse of nature, although knowing well the consequences of sleeping. Travellers on horseback are peculiarly liable to be overcome by this propensity to sleep, when the cold is very intense, in which case they are sure to be frozen to death.

There prevails among many mammalia a singular internal modification, which cannot be explained by any cause more general than itself, but must be referred to some unknown original constitution. We refer to that state of torpidity commonly called Hybernation. See that article.

SLIPPER-PLANT,—botanically *Pedilanthus*. A genus of curious, South-American, evergreen undershrubs, of the spurge order. Six or seven species, all about 20 inches high and apetalous, have been introduced to the dry stoves of British gardens. They thrive in any common soil, and are propagated from cuttings. The name alludes to the flower.

SLIPPERWORT. See Calceolaria.

SLIPPING. See Abortion.

SLIT-PLANTING. See Planting.

SLOANEA. A genus of tropical ligneous plants, of the lime-tree order. The tooth-leaved species, *S. dentata*, is a South-American evergreen timber-tree, of commonly about 40 feet high, and was long ago introduced to the botanical collections of Britain. Seven other species are known.

SLOE-TREE. See Blackthorn.

SLOUGH-HEAL. See Self-Heal.

SLOUGH-IN-THE-EYE. See Inflammation.

SLUG,—scientifically *Limax*. A group of small, creeping, soft-bodied animals, constituting, together with the snail or helix group, the terrestrial, pulmonious, gasteropodous family of molluscs. Both groups, or at least some very abundant species of them, are well known to gardeners and farmers for their extensive depredations on herbaceous cultivated crops. The most common

slugs are *Limax agrestis*, of a greyish colour, without any spots, and from one inch to two inches long,—*Limax cinereus*, of a greyish or dusky colour, with spots or stripes of a darker hue, and from 3 to 5 inches long,—and *Limax ater*, of a jet black colour, and wrinkled on the back, and very commonly crawling about in wet weather; and the most common snails are *Hilex aspersa*, which has a dull coloured shell, marked with three faint mottled brownish bands, and a white rim round the aperture, — and *Hilex hortensis*, which is much smaller than the preceding, and has a glossy shell with distinct bands of vivid colours, and a brown rim round the aperture, and which, in spite of its name of hortensis, frequents the field much more than the garden.

Slugs and snails differ from each other in the latter having shells and the former not; and they agree in shape, in general conformation, and even in most of their minute characteristics. They have four tentacula placed in front of the head, and which, by a singular process of inversion, can be drawn entirely within it. The superior pair are always the longest; and they carry near the tips, but a little on one side, each a small eye, by which the animals distinguish objects nigh at hand. With the inferior pair, they feel and try the road which they have to travel. Between and under this pair is situated the mouth, guarded by two swollen lips, in which, perhaps, the sense of taste may reside. The mouth is armed above with a semilunar horny jaw, placed transversely, and having its outer or cutting edge furnished with one or several serratures. Within the mouth, stretched upon a protuberant, fleshy, buccal mass, the tongue is laid, shaped somewhat like the bowl of a spoon, and consisting of a thin membrane reticulated in a manner so exquisitely regular and minute, that no one can examine it without admiration. On the right side, or neck, of the slug and snail there are three apertures. "The largest, which is the respiratory orifice, is situated at the edge of the shield: the second is at the posterior and upper margin of this first orifice; it is the anus: the third is either placed directly under the pulmonary opening, or immediately behind the upper tentaculum; it is the exit for the organs of generation." The skin is soft, and lubricated with a viscid mucus, which is secreted most copiously when the animals are in motion; and running down on the ground, it serves to smooth the way, and leaves a glistening tract behind, which may lead to the discovery of their retreats. They are strictly gasteropodous, crawling at a slow pace on the flat sole which constitutes their foot and belly. This foot is very muscular, and all its fibres aid in the act of locomotion; but progression is principally performed by a pair of muscles which extend from the tail to the fore part, running along the middle of the foot. On opening the cloaks, they are seen projecting on the interior surface of the foot as two raised lines, larger before than behind. By putting a slug into a bottle partly filled with water, the regular contractions of these longitudinal muscles may be distinctly seen, recalling to recollection the apt comparison of Swammerdam, — "following each other like the waves and billows of the sea." These animals are hermaphrodite and oviparous. They deposit their eggs under clods of earth, loose stones, or in the ground, in which the parent digs with its foot a circular hole, about one inch deep. The eggs vary from twelve to thirty in number; they are white, oval or round, about the size of a common shot, with a smooth soft skin, which is entirely membranous in the slugs, but in the snails contains innumerable minute calcareous grains always in a crystalline state, and usually of a rhomboidal figure. They are, in ordinary seasons, hatched in about three weeks after being laid, but the time is regulated much by temperature, so that in cold seasons it is greatly retarded. The young issue from the egg in the likeness of their parents, active, and furnished with every organ; and the young snails have even then a shell fitting their size and strength. To what length of years the life of a snail or slug is prolonged has not been determined. It is a gross error to suppose that the marks on the shell, which indicate the successive stages of its growth, indicate also the tenant's age; every space between two such marks being said to be formed in one season. This is not the case. These creatures are very patient of injury, recovering after the cruellest wounds; and they are capable of repairing their broken shells, and of reproducing such parts of their body as may have been cut away in the perils to which they are exposed. In winter, they retire under stones and clods, or into crevices of walls. The slugs become merely less active and more hebetous than usual; but the snails properly hybernate; and to protect them from annoyance during this dead sleep, of a winter's continuance, they seal up the apertures of their shells with a horny membrane.

The natural uses of the slug and the snail appear to be, to serve as food for reptiles, birds, and the smaller quadrupeds, such as foxes, badgers, weasels, hedgehogs, &c. The blackbird and the thrush are remarkably fond of them; and may be seen flying off with snails in their bills, and breaking the shells against stones or the branches of trees. There is some apparent reason for supposing that the worm is more useful than injurious to plants, but none that we know of as far as respects the slug or the snail. These animals retire under the cover of foliage or some other protection from the sun and dry air during the day, and come abroad to feed during the night, after rain, or when the weather is cloudy. They select, in preference, tender seedling plants, or the leaves of maturer plants which have become tender and somewhat sweet by incipient decay. They are very fond of greasy

matter, and where a snail has been killed by crushing, its remains attract numbers to feed on it.

To destroy snails in gardens, the only effectual mode is hand-picking, either in the evening or early in the morning, or immediately after rain. Empty flower-pots, reversed and distributed over the surface, if an opening is left on the side, by making a small depression in the soil, will attract a great number of snails; and the more so, if some greased cabbage leaves be placed under the pots. In the course of the autumn, winter, and early in the spring, all their hiding-places should be searched, and the animals taken out and destroyed by crushing or by giving them to swine, which are said to be very fond of them. Hedgehogs and weasels, being their natural enemies, may be kept in gardens; and poultry which do not scratch, such as turkeys, ducks, &c., may be admitted occasionally; though no mode of subduing the snail but hand-picking is to be depended on.

Slugs in gardens are destroyed with less labour than snails; because, their bodies being comparatively unprotected, they are liable to be operated on by any caustic or bitter liquid as readily as worms. Cabbage leaves in a state of incipient decay, with the side which is to be placed next the soil rubbed over with greasy matter of any kind, or even with the bruised bodies of recently killed slugs, distributed over any surface, will attract them in great numbers during the nights; and if the blades are examined every morning, and the slugs which are found destroyed, the piece of ground so treated will soon be freed from them. Pea haulm being very sweet when in a state of incipient decay, forms a powerful attraction to slugs; and if handfuls of it are distributed over a piece of ground in the same manner as cabbage leaves, the little heaps of haulm may be examined every morning, and the slugs shaken from them, and then destroyed by watering with lime-water. Thin slices of turnips or potatoes, placed under inverted empty flower-pots, form an excellent attraction, as do the dead bodies of slugs themselves, some parts or the whole of which are greedily devoured by the living animals. Where slugs are very abundant in a soil not covered with plants so large as to shelter them, as for example with rising seeds, the slugs may be destroyed by watering the soil thoroughly with lime-water or tobacco-water, late in the evening or early in the morning. Abundance of water should be applied, in order that it may sink into the soil, which the slugs penetrate one foot or more in depth, according to its state of pulverization. Quicklime has been laid round plants to protect them from snails and slugs, but it soon becomes mild, and of no use as a protection. Coal ashes and sawdust annoy slugs by sticking to their feet; but they will not be deterred by this annoyance so effectually as to starve for want of food. Soot is also a great annoyance to slugs; but, to keep them from a plant, it requires to be frequently and liberally renewed. "A stout, coarse, horse-hair line, such as is used for hanging clothes out to dry, coiled round the stems of wall-fruit trees, and stretched along the wall will operate as a protection to the fruits from both snails and slugs, in consequence of the bristly surface presented to them, and which they shrink from encountering. Care must, of course, be taken that they do not get under it."

No gardener ought to rest content with merely protecting his plants or fruits from snails or slugs; because, while they are in the garden, as they must live, if they are debarred from attacking one plant, they will only have recourse to another. Nothing short of extermination, therefore, ought to satisfy him; and this he may accomplish by enticing the larger slugs into empty pots, or under cabbage leaves or haulm, and by soaking thoroughly with lime-water the soil which he supposes to contain young slugs or eggs.

The destroying of slugs in fields may be effected by widely different means, and ought, in each particular case, to be attempted by whatever one of these may be most economical in itself and most suitable to the kind and condition of the crop. A good powdering of quicklime on turnips and some other crops, in places where lime is cheap and has not already been over-applied, is a very ready and perfectly efficient means. An aspersion with lime-water, especially after nightfall, may be eminently suitable in the case of some kinds and conditions of crop where quicklime might do harm. A sprinkling of tar-water or of the liquid refuse of gas-works is also effective. The turning in of a large flock of geese, ducks, or other similar feeding fowl is, in some circumstances, the easiest and cheapest method. And an application of common salt may be hopefully made in almost any case, or as a pretty sure resource when any less expensive means is unsuitable or cannot be obtained.

To prevent the appearance of slugs, however, is far better than to destroy them; and may, in general, be more or less certainly effected by the easy expedient of early ploughing. "It would be of some importance," says an intelligent provincial writer, "to know whether the slugs which injure the corn arise chiefly from between the furrow slices in the corn field, or whether they chiefly come from the neighbouring grass fields to the corn. The fact that slugs, as far as I know, never injure corn after fallow, but always after lea or clover, seems to favour the former supposition; but the injury done in gardens by them, where they must come chiefly from without, seems to favour the second hypothesis. The most important indisputable fact is, that they injure only the tenderest blades. After warm and showery weather in May has caused a rapid growth, the corn blades are very tender, and the slug finds them a pleasant food. The tenderness

of the plants is greatest when they are very young. Hence late plants, which have rapidly sprung up under the heat of May, will be more tender than plants which formed their leaves earlier when less heat and moisture were present. This shows the importance of early sowing, especially on lea, if it puts the plants beyond the reach of the slug. But again, the fact that wheat after fallow is not infested, while wheat after lea, or clover, or beans, is sometimes nearly destroyed by slugs, bears in upon the mind the conviction that the slug arises from the soil on which these crops grew. It would lead one to conclude that they, like the grubs, lay their eggs in the soil where they fed during the former season, and that these eggs yield young slugs at some very early period in the season. The fact of my finding many slugs, no bigger than large pin heads, in the grass in February, favours this notion. The inference from this is, the importance of early ploughing for spring crops. Early ploughing, where the ground is exposed to the winter frost, is a substitute for lea fallow to a certain extent. And where wheat is sown early, and after ploughing lea or clover, the plants rise before the ground has had the advantage of this partial fallow. The practice of grazing sheep in winter tempts us to defer ploughing our lea as long as possible. This must be very bad economy if the above views be at all correct; for all that we can gain from them by winter pasture will not exceed 6s. or 7s. per acre at farthest,—and in seeking to gain this, we may lose ten times as much by the grub and slug in our next crop; and it is hardly possible to conceive that our loss will ever be so little as double the gain from pasturage."

SMALLAGE. See Celery.

SMALL-POX. This disease has lately been making great ravages among the sheep of Britain. The form of it which attacks sheep, and which is called by the learned *Variola ovis*, has long been known and dreaded on the Continent, and seems to have been recently imported thence into this country. The Marquis of Salisbury in Hertfordshire speedily lost nearly 2,000 sheep by it; some of the farmers of Norfolk soon lost 50 per cent. or even a larger proportion of their flocks; and the farmers of some entire districts have felt themselves exposed to so much danger, by the diffusion of the epizootic from diseased sheep in the public markets, as to be compelled to sell their stock only on their own farm, and to refrain from either selling or purchasing at fairs. But on account of the consequent embarrassment which has occurred to the sheep-trade, as also on account of the risk occasioned to the public health by sending diseased sheep to the shambles, and likewise on account of the contemporaneous prevalence of pleuro-pneumonia among cattle, the attention of the Legislature has been drawn to the sanitary condition of the live stock of the country, so that public facilities will henceforth be afforded to prevent the spread of contagion. In Germany, the law directs all owners of flocks affected with small-pox, not only to tell the fact to their neighbours, but to proclaim it in the newspapers; and so stringent a provision was probably suggested by the fact, that any sheep, on passing from an infected district to an uninfected one, may carry abroad and widely diffuse the virus of the malady before any symptom of the existence of it in its own body can be observed.

All persons engaged in sheep husbandry ought to acquaint themselves well with the symptoms and proper treatment of small-pox in sheep, both that they may avoid purchasing diseased animals, and that they may know what to do if it should break out among their flocks. We shall, therefore, present one account of it by a German agriculturist, and another by a very experienced veterinary surgeon of Hamburg. "In this disease," says the former, "the sheep suffer previously internally, with a loss of appetite, heaviness, and indisposition to move, difficulty of breathing, swelling of, and discharge from, the eyes, and of a viscous matter from the nostrils. In from three to five days, spots appear on the bare parts of the legs and body, which become large, and form blisters, in the centre of the red circumference of which yellow spots come, and at last fill with yellow matter. If these spots become blue or blackish, they unite, and a thin stinking matter issues from them, which is the height of the disease; but death ensues if the pustules should not come properly out, or should strike in again. The last stage of the disease, when it terminates favourably, is marked by the drying away of the sore, on which a black scurf forms and falls off. The animal has the disease, as with man, only once; in a flock it is contagious, but not so among cattle. During this disease, good hay and drinks of a decoction of barley are good, to which a little common salt may be added. At the commencement of the disease, the nose and mouth must be kept clean with vinegar and water, the eyelids are to be often washed with warm milk, and an electuary, of three-parts of flower of brimstone and one part common salt and honey, is a useful remedy. But I am of opinion that inoculation of the whole flock the moment the disease shows itself, even in one in the neighbourhood, is the only preservative." The surgeon of Hamburg says:—"The first symptoms are, that the animal becomes lame or stiff in the hind legs, is uneasy, will not feed, &c. After this the fever commences, with shivering and trembling, with increased heat of the body; but the ears and tail particularly become very red; the nostrils and gums dry hot; the animal stands with drooping head, and the feet are close together under the belly; it is lame, or halts, particularly with the hind-legs; the ears hang, the eye is bloodshot; the fever increases, as also the difficulty of breathing; the animal feeds and ruminates little,

or not at all; its dry dung passes in very small, hard balls. Soon after the first attack of fever, there appear on all the bare parts of the body, particularly about the mouth, eyes, and on the inner surface of the leg and belly, and the under part of the tail, numerous small spots, like flea-bites, which in eight or nine days come more out in small pimples, and in form like the head of small-pox. As the spots become more numerous, the swelling of the head increases, so much so that the animal can but with difficulty open its mouth and eyes; the lumps that have formed fill, in three or four days, with a pale, clear, white matter. The pustules now formed are of a good sort, and differ in size up to that of a pea. They are found mostly on the parts of the body with no wool on, but they may be even found under the wool. The malignant pustules are found close together, of a red, violet, blue-blackish, or brown-red colour, with a blue margin; they are broad, flat, and sunk in, and emit an offensive smell. The animal stands unsteady, with drooping and swollen head, and closed eye; the nostrils are stopped up with a tough, viscous matter, smelling like carrion; it breathes very short and with difficulty, snorts with open mouth, gnashes its teeth, and its evacuations emit a very offensive odour; in this latter state, a cure is impossible. On the first attack of the common 'variola,' the animal must be well taken care of, and must not be exposed to cold or wet, and drinks must be administered to it of salts, bitters, and spices. As a preventative, inoculation with healthy matter, if obtainable, is the best, as thereby the inoculated animal throws out only a few of the pustules, the sickness from which it easily gets over, and is then completely protected from the attacks of the disease." Mr. Simonds, the lecturer on cattle pathology, in the Royal Veterinary College, also says that inoculation may be said to be our chief means of controlling the disease. Vaccination has been tried, but is not to be depended upon. The practical results are, that farmers should spare no pains to avoid buying infected sheep,—that they should invariably keep all newly bought animals separate from their own stock, until time shall have been afforded for the development of disease, if it exists,—and finally, that should the disease appear, not a moment should be lost in calling in the veterinary surgeon, and subjecting the whole flock to inoculation.

SMEARING. See Salving.

SMELL. See Nose.

SMILACINA. A genus of hardy, ornamental, perennial-rooted, herbaceous plants, of the smilax order. Nine species, varying in height from 3 to 25 inches, and carrying either white or yellow flowers in summer, have been introduced to Britain, principally from North America; and all love a soil of sandy loam or of somewhat humous loam, and are propagated by division of the root.

SMILAX. A genus of climbing, monocotyledonous, exotic plants, constituting the type of the natural order Smilaceæ. This order is very nearly allied to the asphodel family, differing from it principally in the trifid style and the membranous seed-envelopes. About a dozen hothouse species, about a score of greenhouse species, and about 80 hardy species at present occur in British collections, and are distributed among 12 genera. A considerable number are highly ornamental or otherwise popularly interesting; and a few are valuably medicinal.

Upwards of 40 species of the genus smilax have been introduced to Britain; and nearly 30 more are known. All or almost all are remarkable for the twining habit of their stems, and for the resemblance of their leaves to those of dicotyledonous plants. Some have prickly stems, and some unarmed stems; and some of both the prickly and the unarmed are angular, and others terete. Four of the most remarkable species are noticed in the article Sarsaparilla; and almost all the other species are interesting only to botanists.

SMITHIA. A small genus of interesting, exotic, annual plants, of the hedysarum division of the leguminous order. Three trailing, yellow-flowered, late-blooming species, the sensitive, the twin-flowered, and the crowded, have been introduced to Britain,—the last from Australia, and the other two from India.

SMUT. A disease of the ears of growing corn, filling the grain with a fine sooty-looking powder in the room of farina. It arises entirely from two minute coniomycetous fungi,—the *Uredo segetum* and the *Uredo fœtida;* but it attacks all sorts of corn, and presents a great diversity of appearance, and bears a number of different popular names, and has been erroneously ascribed, by all classes of cultivators, to a great diversity of causes. Some farmers, seeing only a very few ears of a crop perceptibly affected with smut, regard the evil as of small consequence, and are totally unaware that when no more than one smutted ear can be found in a sheaf, the straw of the apparently sound plants may want so much as one-third of its average weight, and the grain so much as three-sevenths; and other farmers, who may have a correct enough opinion of the mischievousness of smut, are so misled by false notions of its cause as either to reject all suitable preventives and remedies of it, or to adopt them empirically and without sufficient confidence and vigour.

Some of the many erroneous causes which have been assigned for smut have no connexion with it whatever; and others are mere contingencies which either aggravate its symptoms or accelerate its progress. One alleged cause is deficient fecundity, in consequence either of the pollen being washed away with rains, or of its undergoing some chemical change of a putrefactive nature; but smut is found to affect the organs of fructifi-

cation, and either to impair or to destroy them, long before the pollen can be formed. Another alleged cause, sanctioned long ago by the distinguished Jethro Tull, is humidity of the atmosphere, or the prevalence of fogs, or the bursting out of intense sunshine while the crop is in a moist condition; but this notion has been disproved by some carefully conducted appeals to experiment,—and is disproved also by the general fact, that smut is sometimes observable in an early stage of the plant's vegetation, long before it has escaped from the leafy envelopes. A third alleged cause is excessive moistness of the soil, —and certainly this, though not a cause, is a very powerful provocative, insomuch that well-drained and thoroughly aerated soils are incomparably freer from attacks of smut than wet ones; but the disease occurs on even the driest land, and may often be observed as rife in the dry parts of a field as in the wet parts. A fourth alleged cause, sanctioned by such high names as those of Somerville, Walker, and Linnæus, is the hatching and feeding of minute insects; but this opinion has been refuted by express and searching observation, and may be exploded also by the general fact that acari and aphides and other minute insects feed more or less on all sorts of plants, whether affected by smut or not, and almost always abound on decaying vegetable matter or on plants which are in a diseased or enfeebled condition. A fifth alleged cause is the abrasion of the seed-corn in the process of thrashing; but seeds thrashed in exactly the same way run to smut in some seasons and do not run to it in others,—and numerous grains of wheat of different sizes have been experimentally bruised with a hammer previous to sowing, and have not been found to produce smutted plants. A sixth cause, alleged by Wolfius, is monstrosity of the embryo; but male flowers, or male parts of flowers, as well as female ones, are liable to smut,—and they have no embryo. A seventh alleged cause is deficiency of nourishment, occasioned by poverty of soil or by crowdedness of crop; but diseases closely akin to smut attack the fructification of some perennial plants whose roots and stems, from year to year, are so vigorous as to indicate the presence of ample nutrition. An eighth alleged cause is fermentation within the ears of corn, occasioned by natural humidity, or by excessive slowness of development and deficiency of evaporation; but, if this were a true cause, it would account for the appearance of smut only after the seeds begin to be formed, and might be expected always to produce the disease in far greater extent than it is generally found to exist. Most other alleged causes either are akin to some of these eight, or are exceedingly fanciful, or confound smut with some other and widely different diseases; and they, therefore, need not be named.

The two species of fungi which produce smut, or whose spores constitute the fine, powdery, sooty-looking substance of the disease, possess a somewhat close resemblance to each other, and are usually described under one general name; yet, not only have they separate specific characters, but they make specifically different developments in corn-plants, and produce essentially different economical effects on crops; and they, therefore, require to be separately studied, and distinctively understood. The *Uredo segetum* has no smell, and is the species popularly called dust-brand, bunt-ear, and chimney-sweeper; and the *Uredo fœtida* has a disgusting smell, and is the species popularly called bunt, stinking-rust, bladder-brand, and pepper-brand;—or, according to a sort of discriminating popular nomenclature, the former is smut and the latter is smut-ball.

The *Uredo segetum* is much more minute than most other coniomycetous fungi which attack gramineous plants; and, in particular, is not half the size of *Uredo fœtida*. Its spores are so extremely small that not fewer than seven millions eight hundred and forty thousand would be required to cover one English square inch. It first so injures the interior portions of the flowers of the plants which it attacks as to render them abortive; it next makes the pedicels or little stalks of the florets swell and become very fleshy; it next consumes the whole of this fleshy mass; and it finally comes through the epidermis and appears between the chaff-scales in the form of a black soot-like powder, and looks as if adhering by means of some gummy substance to the young ear. It operates alike on wheat and barley and oats, and is essentially the same in them all; but it differs widely in aggregate coherence upon wheat and barley,—and differs also in the microscopic appearance of its spores,—but probably owes the differences entirely to the different action of the matrices in which it grows. It commonly attains maturity some weeks before the crop which it infests is ready for the sickle; and it then is a loose light powder resembling very fine lamp black, and is swept away and scattered by the winds,—so that, even when it has made great havoc upon a crop, it is seldom seen to any considerable extent at the time of harvest. It has sometimes been found to attack the leaves and the culms of corn plants; but, in general, it attacks only the ear,—and this it completely destroys. It is comparatively rare in wheat, and does not seem to occur at all in rye, but is very common in barley, and still more so in oats. It has also been observed in several of the forage grasses. Some farmers absurdly think that a little of it in the barley crop is a good sign; and most regard it as far less mischievous than *Uredo fœtida*. But, in so far as it exists, it is always and entirely a desolating evil; and it both escapes the observation of superficial observers, and eludes some of the common methods of preventing or extirpating it, by the early maturation and profuse dispersion of its spores; and though really

a less evil comparatively than *Uredo fœtida*, it is a much greater one absolutely than most farmers suppose.

Grain containing some mixture of smut has not been observed to injure fowls who eat it; and yet the straw of smutted plants is asserted to be distasteful to cattle. The effect of the fungus upon the wholesomeness of crops, in fact, is little understood, and does not seem to have been tested by any good published experiments; yet it may be pretty closely estimated by reference to the known chemical composition of smutted grain. "Chemical analysis has demonstrated that the *Uredo segetum* effects an entire decomposition of the vegetable constituents of the grain it infects, the saline constituents of the grain remaining nearly unaltered. Parmentier, Cornet, Girod Chantrans, Fourcroy, and Vauquelin, have successively examined it, and the result of their researches is, that smutted grains of wheat are composed, first, of about one-third their own weight of a green, butyraceous, fetid, and acrid oil,—second, nearly one-fourth of a vegeto-animal substance, perfectly similar to that which comes from putrid gluten,—third, a black coal, one-fifth of their weight, similar to that which is found in all remnants of putrified organic compounds,—fourth, free phosphoric acid, amounting scarcely to more than ·004 of the smut,—and fifth, phosphates of ammonia, magnesia, and lime, in the proportions of a few thousandths. 'We must remark,' say MM. Fourcroy and Vauquelin, 'that, in one examination of putrified gluten, we found characters very similar to those of the smut of wheat; and that the products of the one are so like those of the other, as to render it difficult, in certain cases, not to confound them together. It requires a man to be well practised in chemical experiments to discern the slight differences that exist between these two putrified matters, because the differences are only delicate shades, not easily discernible. The contagion attacks especially the gluten, and precedes, indeed prevents, the formation of the starch; since we know positively that this fecula, no traces of which are found in the smut of wheat, suffers no alteration from that septic process, which so powerfully attacks the glutinous substance.'"

The *Uredo fœtida* occurs only in the grain of wheat, and is a well known and much dreaded disease. It may be detected in the young seed, even in the very earliest states of the flower-bud; and when fully ripe, it most frequently occupies the whole interior of the grain. "The earliest period at which I discovered it within the cavity of the ovule of a young plant of wheat," says M. Bauer, "was sixteen days before the ear emerged from the hose, and about twenty days before the sound ears, springing from the same root, were in bloom. At that early stage, the inner cavity of the ovum is very small, and, after fecundation, is filled with the albumen or farinaceous substance of the seed, and already occupied by many young fungi, which from their jelly-like root or spawn, adhere to the membrane which lines the cavity, and from which they can be easily detached in small flakes, with that spawn. In that state, their very small pedicels may be distinctly seen. At first, the fungi are of a pure white colour; and when the ear emerges from its hose, the ovum is much enlarged, but still retains its original shape; and the fungi rapidly multiplying, many of them have then nearly come to maturity, assumed a darker colour, and, having separated from the spawn, lie loose in the cavity of the ovum. The infected grains continue growing, and the fungi continue to multiply till the sound grains have attained their full size and maturity, when the infected grains are easily distinguished from the sound ones, by their being generally larger and of a darker green colour; and if opened, they appear to be filled to excess with these dark-coloured fungi. But the grains infected with the *Uredo fœtida* very rarely burst, and these fungi are seldom found on the outside of the grain; but if a grain be bruised, they readily emit their offensive smell, which is worse than that from putrid fish. When the sound grains are perfectly ripe and dry, and assume their light brown colour, the infected grains also change, but to a somewhat darker brown, retaining, however, the same shape which the ovum had at its formation, the rudiments of the stigma also remaining unaltered." The spores which fill the grain constitute a fine, black, disgusting, fetid powder, and amount to about four millions in a single grain, and may be easily distinguished and examined through a microscope, and have then the appearance of articulated globules growing in a bundled manner upon threads; but the sporules which they contain, and which propagate the smut in the same general way in which seeds propagate phænogamous plants, are so surpassingly minute as to be scarcely distinguishable under very high powers of the microscope, appearing then only like a faint cloud or vapour in a puffy escape from the spores.

The *Uredo fœtida* not only destroys all the grains or plants which it directly attacks, but greatly deteriorates the value of the sound part of the general crop. The disgusting odour which it emits may be perceived on passing through a field where it prevails; and becomes cohesive to the fingers and intolerable to the sense when an infected ear or two are broken in the hand; and diffuses itself sufficiently through the sound grains by the contacts of growing and harvesting to render the flour made from them perceptibly malodorous and comparatively unfit for bread. Ready purchasers, however, are found among the manufacturers of gingerbread, who have discovered that the treacle, and whatever else they mix up with it, effectually disguise the odour of the fungus; and while such a mode

of employing the tainted flour would be perfectly unobjectionable if the odour were innoxious, it becomes censurable and wicked when good reason exists for suspecting the odour to be seriously unwholesome.

The sporules of both *Uredo segetum* and *Uredo fœtida* were long believed and have recently been proved to find their way into corn-plants by entering their spongioles with the moisture and ascending their interior with the sap. "There is little doubt," says Mr. George W. Johnson, "but that the mode in which smut is imparted to the plant is by its roots imbibing the extremely minute seeds of the fungus along with the moisture of the soil; and this opinion is confirmed by the observation that the disease is most prevalent when the winter has been mild, and the spring wet,—for in such seasons the abundant moisture passing through the soil is most likely to convey the seeds to the mouths of the plant's radical fibres." "That the sporules enter by the roots and circulate in the plant," says the Rev. Edwin Sidney, "has been the surmise of most observers; but no one has yet seen them grow; nor would this be the normal mode of growth. The spores themselves are undoubtedly too large to enter either by the stomata of the leaves, or the spongioles of the roots. Some ingenious experiments have been recently made by Mr. Berkeley, which he most kindly communicated to the author, that appear to establish the theory that these contents of the spores do enter the plant in the way suspected, and grow. The mode of proceeding was to immerse some seeds of wheat in water containing bunt. One of the first appearances was a curious mould with peculiar spores that sprung upon the spores of bunt. The plants which came up from these seeds were evidently affected; but no communication whatever could be traced between the cells of these plants and the shoots thrown out by the spores. No intrusion whatever of the mycelium developed by the bunt spores into the wheat could be discovered. This looks, therefore, as if the fine contents of the spores do certainly propagate the fungus." "Although the bunt-fungus confines its attacks to the young seed," says Professor Henslow, "it seems to be a condition essential to its propagation, that it should be introduced into the plant during the early stages of its growth, and that its sporules are most readily absorbed by the root during the germination of the seed from which the plant has sprung. It has been clearly proved that wheat plants may be easily infected, and the disease thus propagated, by simply rubbing the seeds before they are sown with the black powder, or spores, of the fungus. It is also as clearly ascertained that, if seeds thus tainted be thoroughly cleansed, the plants raised from them will not be infected; and this fact is now so well established, that the practice of washing or steeping seed-wheat in certain solutions almost universally prevails."

The following table, compiled from a paper in the Farmer's Journal for June 1828, shows the highly infectious nature of smut, and the good effects of pickling:—

I. Wheat merely put into the bag where smutted wheat had been.

Old wheat,	1 in 30	smutted
New Kentish red, kiln dried,	1 in 20	do.
Yellow Lammas, do.	1 in 3	do.
Spring wheat, having a small quantity of smut-powder shaken amongst it, more than	1 in 2	do.

II. Wheat when moistened rubbed with smut-powder.

Old red wheat,	1 in 7	smutted
New do.	1 in 6	do.
Do., kiln-dried,	1 in 8	do.
White wheat, do.	1 in 3	do.
Yellow Lammas, do.	1 in 7	do.
Spring wheat, do.	8 in 10	do.

III. Wheat when moistened rubbed with smut-powder, but afterwards, previous to sowing, washed in a solution of vitriol and chamber-lye.

Old wheat,	1 in 2,000 smutted
New wheat,	Clean.
Do., kiln-dried,	Clean.
White wheat, do.	Clean.
Yellow Lammas, do.	3 in 2,000 smutted

The chief preventive of smut in wheat is the steeping of the seed-corn in some suitable solution. The spores which, at the time of thrashing, are dispersed from smutted ears in the form of a fine powder, and which attach themselves to the sound grains, adhere with considerable obstinacy by means of an oily or greasy matter in their own substance, and cannot be thoroughly cleaned away except by means either of an alkali which shall combine with the oily matter and convert it into soap, or of some powerful substance which shall be adverse enough to vegetable life to kill the spores and yet not so adverse as to kill or injure the grains. The substances most commonly employed in alkaline steeps are lime, and salts of soda, potash, and ammonia; and those of a killing kind most commonly employed are arsenic, sulphate of copper, nitric acid, muriatic acid, and sulphuric acid. The use of poisons, however — particularly violent ones — is altogether unnecessary, and very dangerous, and not a little culpable; and the use even of excessively pungent substances, which are not strictly poisonous, is never so politic, and perhaps never so efficient, as that of the alkalies or of common salt or of some mixture of saline substances. The following table shows the results of extensive and accurate experiments, conducted by Mr. Bevan, in the growth upon a sandy soil at Leighton in Bedfordshire of specimens of wheat-seed steeped in a variety of liquids,—the columns A showing the results from sound grain, and the columns B showing those from smutted samples:—

LIQUIDS EMPLOYED.	Specific gravity of solution.	Number of smutted ears in three sheaves.		Bushels of good wheat per acre.		Cwts. of straw per acre.	
		A	B	A	B	A	B
Solution of potash,	1·357	1	81	21·6	13·6	36·6	29·1
muriate of potash,	1·097	3	218	20·2	10·1	36·0	21·1
nitrate of potash (saltpetre),	1·080	7	115	23·8	14·3	36·9	31·9
soda,	1·056	9	159	20·2	11·7	35·6	26·7
muriate of soda (common salt),	1·089	—	290	24·0	14·5	41·5	33·3
sulphate of soda (glauber salt),	1·047	12	241	21·6	12·3	38·5	27·8
muriate of ammonia (sal ammoniac),	1·026	1	150	19·8	17·6	35·4	30·2
common soot,	1·025	—	123	20·8	11·4	34·8	25·3
lime, saturated,	1·003	—	2	21·9	12·4	38·7	25·9
nitric acid (aquafortis),	1·016	The seed treated with this acid did not vegetate					
muriate acid (spirit of salt),	1·011	—	136	20·7	16·1	35·7	34·1
sulphuric acid (oil of vitriol),	1·050	—	—	20·4	17·8	35·4	37·1
Dry, in its natural state,	—	6	323	20·3	14·7	35·7	31·1
Washed in common water,	—	None sown.	107	—	18·3	—	35·8

"The experiments of Mr. Bevan," remarks Mr. George W. Johnson, "indicate that lime water is the most effective of these preparations; and if this be adopted, it may be prepared by mixing one pound of fresh lime with three gallons of boiling water, allowing these to stand for two hours, and the clear liquor then to be poured off, and immediately used. In this liquor the wheat should be soaked for twelve hours, stirred twice or thrice during the time, and then mixed, upon a floor, with the powder made by pouring three gallons of boiling water upon five pounds of lime. I have had no experience of the effects of lime-water as a preventive of the smut; but with stale urine and a solution of common salt, I have witnessed numerous and extensive experiments. The results, without exception, were favourable and nearly similar; and this being the case, a preference is to be given to common salt, as being decidedly the most cleanly and the least disgusting. The mode I have observed to be the most effective, is to wash the seed with pure water, pouring this off with all the floating grains, and then allowing the seed to soak for twelve hours in a solution of common salt, having a strength, or specific gravity, sufficient to float a common hen's egg." A solution of sulphate of soda, in co-operation with an application of lime, was found by M. de Dombasle, after many experiments, to be the most efficient steep. The solution requires about $17\frac{3}{4}$ lb. of the sulphate in 22 imperial gallons of water; and as this salt does not very readily dissolve, the solution ought to be commenced a day or so before it is wanted, and frequently stirred till all the salt is dissolved. "The grain is to be formed in heaps on a floor, which are to be completely moistened with the above wash by means of a watering pan with a rose head. During the time the wash is being poured over the heaps of grain, they must be kept constantly stirred about by means of wooden shovels, till the whole be perfectly moist, which is known by the wash running from the heaps after they are sufficiently saturated. After the grain is well moistened, lime in powder is to be immediately thrown over the heaps, in the proportion of nearly $4\frac{1}{2}$ lbs. to the 22 gallons, imperial, of grain; this is done gradually, while the grain is to be turned over in every direction, so that the whole may be intimately combined. When this is done, the grain may be either sown immediately, or kept for some days, in which case it may be turned over every three or four days."

The use of any kind of steep, however, is a preventive of smut only as propagated by the adhesion of spores to the grains of the seed-corn, and can have no efficiency whatever against the germination of spores which lie lodged in the soil independently of the seed-corn. "Although it is very apparent," says Mr. George W. Johnson, "that the smut is generally imparted to a wheat crop by the agency of the seed sown, yet I am by no means of opinion that this is the only source of infection. I have kept ears of wheat that were covered and destroyed by the *Uredo*, during more than twelve months, in a situation where they experienced the vicissitudes of temperature during all the seasons, unprotected by more than the paper envelope in which they were suspended in an outhouse. Yet when the *Uredo* that had been thus exposed was mixed with healthy, well-washed seed-wheat, this produced diseased plants in a triplicate proportion more numerous than that not so mixed. This experiment demonstrates that frost and drought, acting in concert with a damp atmosphere, do not destroy the vegetating power of the *Uredo's* seed. Such being the fact, why may not this seed remain in the soil ready to impart the plague? We know that, owing to its extreme lightness, this seed floats buoyantly in the air, and may be carried by winds to distant soils, which, in the autumn of the same year, before any extremity of cold has been endured, will have to bear the wheat crop for the following harvest. The opinion that the soil is one source of infection, is sustained by the fact that fields in the vicinity of the sea are rarely injured, and never extensively, by the ravages of the smut. Such soils are impregnated more than any other with common salt, and the effect of this saline compound upon the *Uredo* has been noticed already." The spores of *Uredo segetum*, too, are so generally shed and dispersed before the har-

vesting of the crop, that they may be supposed to lie lodged in immense numbers in every part of the field or farm or district where they were produced; and even in so far as they adhere to the grains of barley and oats in the same way in which those of *Uredo fœtida* adhere to the grains of wheat, they have such a peculiarly strong hold in connexion with the integuments of these grains that they cannot very readily be reduced or killed by means of steeps. As regards some smutted wheat lands, therefore, and especially as regards all smutted barley lands and all smutted oat lands, other preventives and remedies must be brought into requisition, and should be such as to secure the utmost possible cleanness of both the seed-corn and the land, and will, after all, be found incompetent to effect an entire cure. "Since the smut-fungus does not confine its attacks to corn, but is also found in the grasses which grow in pastures and by the road-side," says Professor Henslow, "a plentiful supply of sporules will always be kept up, to warrant our believing that we shall never expunge this species from the British Flora. Still we may feel assured that precautionary measures may materially lessen an evil which cannot be wholly avoided. Since the sporules of the two fungi which produce bunt and smut enter the plants they attack by absorption at the roots, and since they are buried with those seeds to whose surface they have attached themselves,—it is evident that too great care cannot be bestowed in procuring clean seed, or in purifying such as may accidentally be infected. From a variety of considerations, it has always appeared to me strange that practical agriculturists are accustomed to pay so little attention to the raising of pure seed-crops. There may be reasons, which I do not properly appreciate, that would render it inexpedient to cultivate a seed-crop apart from the rest of the produce raised on a farm; but I should have thought that it was always worth while for every farmer to set aside some portion of ground to be more carefully tended than the rest, for the purpose of securing good and perfectly clean seed. Among other reasons for such a practice, he would then be able to weed his crop from every plant infected with bunt or smut, before the fungi ripened." The obtaining of seed-corn for any farm from other and distant soils is recommended by Tull, Donat, Lignerolle, and others; but, however beneficial this may be for securing other desirable effects, it can be useful in regard to smut only when the seed-corn is brought from a district remarkably free from that disease. All the preventives and remedies which address themselves to the state of the land, or consist in special processes of georgy and special methods of culture, are the same in the case of smut as in the case of mildew. See the article Mildew.

SMYRNIUM,—popularly *Alexanders*. A genus of herbaceous plants, of the umbelliferous order. The common species, *Smyrnium olusatrum*, grows wild on the rocks by the sea-shore in many parts of Britain, and has a place in gardens as a culinary plant. Its root is biennial; its stem is furrowed, branched, and 3 or 4 feet high; its lower leaves resemble those of smallage, but are much larger, and have rounder and serrated lobes; its upper leaves are trifoliate, and similar in form to the lower, but smaller; its flowers grow in large umbels at the ends of the branches, and bloom in May and June; and its capsules are large and roundish, and contain each two moon-shaped seeds. The whole plant has a strong warm taste; and its blanched stems are used in salads and soups. Crops are raised from seeds sown in spring in drills; and the plants may either remain or be transplanted into shallow drills at distances of 15 or 18 inches from drill to drill and of 5 or 6 from plant to plant, and must be earthed up in the same manner as celery.—Five or six ornamental species, all hardy and either biennials or perennials, and varying in height from 12 to 40 inches, and mostly carrying flowers of either yellowish or whitish colours, have been introduced to Britain from Caucasus, Continental Europe, and North America.

SNAG. The stump of a stem or lower part of a branch left in very free pruning.

SNAIL. See Slug.

SNAIL-COD. A soft, silty deposit on the bottom of deep rivers, abounding in molluscs and shells, and serviceable as manure. See the article Sea-Ooze.

SNAIL-FLOWER. The caracalla kidney-bean. See the article Kidney-Bean.

SNAKE. A tribe of ophidious reptiles. It comprises all serpents, whether venomous or non-venomous, whose sub-caudal plates are arranged in pairs; and even exclusive of all venomous species, it is so enormously numerous as to have put the ingenuity and inventiveness of naturalists severely to the test to subdivide and classify it. Eleven genera of non-venomous snakes are enumerated by Cuvier. The common snake, *Coluber natrix*, is a native of Britain, and occurs in bushy places and in banks near water. It is from two to three feet long. Its back has a dusky colour; and its belly is beautifully variegated with black and bluish stripes. It has two rows of small serrated teeth; but has no fang, and is perfectly harmless. It feeds on insects, frogs, field mice, harvest mice, and vegetable substances; and ought to be regarded as friendly to the farmer by destroying some of the pests of the field. See the article Reptiles.

SNAKE-GOURD,—botanically *Trichosanthes*. A genus of exotic, trailing, annual plants, of the cucumber order. Five or six white-flowered species have been introduced to British collections from India and China; but they do not possess any particular interest.

SNAKE-ROOT,—botanically *Ophiorhiza*. A tropical, ornamental, white-flowered, evergreen shrub of the madder family. It was introduced

to British hothouses about 28 years ago from India; and it has a height of about 3 feet, and blooms from the beginning of summer till the middle of winter. It constitutes a genus of itself. The name snake-root is borne also by a plant of the birthwort genus. See the article ARISTOLOCHIA.

SNAKE'S-BEARD,—botanically *Ophiopogon*. A small genus of curious, half-tender, evergreen herbs, of the smilax family. Two species, of respectively about 12 and 20 inches high, have been introduced to Britain from China and Japan.

SNAKE'S-HEAD. See FRITILLARY.

SNAKE'S-TONGUE,—botanically *Lygodium*. A genus of exotic ornamental ferns, of the gleichenia tribe. Seven or eight species have been introduced to the hothouses of Britain from the Indies and Continental America; and nearly twenty more are known. Most of the introduced species are flexible twiners or climbers of about 6 feet in height, and possess a high degree of elegance.

SNAKEWEED. See BISTORT.

SNAKEWOOD. A small genus of ornamental, tropical, evergreen trees, of from 20 to 35 feet in height, of the nettle family,—*Cecropia;* also, a Bahamese, evergreen, timber-tree, of about 20 or 25 feet in height, of the redwood genus,—*Ceanothus colubrinus*.

SNAPDRAGON,—botanically *Antirrhinum*. A genus of ornamental herbaceous plants, of the figwort family. Two species grow wild in Britain; eight or nine have been introduced from Continental Europe and California; a few more are known; and very many, which formerly ranked as snapdragons, are now included in the genera linaria and nemesia. One of the indigenous and two of the introduced species are annuals of from a foot to two feet in height, with respectively carmine, red, and variegated flowers; two of the introduced species are small, evergreen, half-tender trailers with white flowers; the other introduced species are hardy erect evergreens, chiefly with pink flowers; and the other indigenous species is a hardy erect evergreen, comprising varieties with respectively pink, scarlet, carmine, scarlet and white, and variegated flowers, and also one with variegated leaves. But the different colours of the flowers are variable in seedlings; and many most splendidly tinted and brilliantly variegated ones are borne by permanent hybrids. Choice old varieties are propagated from cuttings; and both the normal plants and new varieties are raised from seeds. All the good kinds are very showy; and many of them rank among the most conspicuous and admired beauties of the parterres of cottages and villas, and of the open borders of large flower-gardens. The perennial sorts flourish best and endure longest upon old walls,—and succeed not amiss upon poor, dry, sandy or gravelly soils; but generally die out in two years, or rot away in the second autumn or winter, on any common garden soil. All the common kinds should be raised from sowings in the early part of March on walls, rocky barren spots, or patches of very poor dry soil, and allowed to remain permanently where they grow; and they will require very little culture, and will continue long in bloom every year, and may be made to render some abject parts of a garden very agreeable.

SNEEZEWORT. See MILFOIL.

SNIFFLES. A disease of rabbits. It proclaims itself by constant sneezing, and by a profuse discharge of mucus from the nose; and, after continuing for a few weeks without seeming to grow worse, it suddenly terminates in pining and death. It arises from confined damp air, and is exceedingly infectious. Whenever it appears in a set of hutches, the affected animals should be killed, the hutches washed with chloride of lime, a better ventilation established, and a fresh stock of rabbits provided.

SNIPE. A group of birds, of the long-billed family of the wading order. It is sometimes understood so extensively as to comprise several genera of the longirostres; sometimes coextensively with the reduced genus scolopax; and sometimes so limitedly as to comprise only the three species popularly called the common snipe, the great snipe, and the Jack snipe. The characters of the reduced genus scolopax—shared by these three species with the woodcock, the red-breasted snipe, and some others—are straight bill, with the point a little inflated externally, and the nasal furrows extending nearly to the point,—compressed head, large eyes placed very far back, and non-palmated feet.

The common snipe, *Scolopax gallinago*, weighs four ounces, and is nearly twelve inches long and about fourteen broad. The bill is three inches long, flat at the end, often rough, and either pale brown or greenish yellow; the head is marked lengthwise by two broad black bands; the chin is white; the neck is variegated with brown and red and fawn; the scapulars are striped on one web beautifully lengthwise, and barred on the other with black and yellow; the quill feathers are dusky, and those next the back are barred with black and pale red; the breast and the belly are white; and the tail coverts are reddish brown, and long, and almost cover the tail. This bird frequents marshes, edges of rivulets, and similar situations in almost all parts of the world; and it ascends out of sight, and utters from a great distance its piercing note, which sounds like the bleating of a goat. In winter, the snipes of Britain are common inhabitants of our marshes and rank meadows, and shelter themselves there among the rushes and other coarse aquatic vegetation. In summer, they disperse to different parts, and are found in the midst of our highest mountains, as well as in our low moors. They begin to pipe in the first week of April. Many of them breed with us; and their nest is composed of dried grass and herbs,

with sometimes a few feathers. They lay four or five eggs, of a dirty olive colour, marked with dusky spots. The young appear ugly and shapeless; and the mother never deserts them until their long bill is firm enough to enable them to procure their food. The cock, while the hen is sitting, poises himself on his wings, sometimes making a whistling, and frequently a drumming, noise; and it is uncertain whether this noise is ventriloquous, or is produced by the motion of the wings. Mr. White says, it happens always when the bird is descending, and his wings are violently agitated. Snipes feed on worms and insects which they find in the moist ground, and also on small snails, which they sometimes swallow whole. They usually have abundance of fat, which is not apt to cloy, and rarely disagrees with those that eat it; and they are cooked like the woodcock, without extracting the entrails, and are every where esteemed for their delicious flavour.

The great snipe, *Scolopax major*, is distinguished from the common snipe by being about one-third larger, and by its fawn-coloured variegations above being smaller, and the brown ones below larger and more numerous. It is comparatively rare in England, and occurs always alone and detached, and is sometimes called the solitary snipe. Some persons have supposed it to be not a distinct species, but merely an old and overgrown common snipe, changed in its plumage from age, and enlarged in its bulk from ceasing to breed.

The Jack snipe or Judcock, *Scolopax gallinula*, is nearly one-half smaller than the common snipe, and has but one black band on the head. Its neck is variegated with white, brown, and pale red; its scapulars are narrow, very long, brown, and margined with yellow; its tail is brown, and has tawny edges; and its legs are cinereous green. It frequents the same haunts and feeds on the same fare as the common snipe; but it is more rare, and lies so close as to incur the risk of being trodden on before it will rise, so that it is very difficult to be found. It never flies far, and has a comparatively sluggish motion.

SNOW. Frozen vapour deposited in powdery globules or in flaky and spicular crystals from the atmosphere. It has the same relation to rain which hoar-frost has to dew or which ice has to water. It is supposed to be formed at no great height in the atmosphere, and while the vapour is collapsing into drops. The powdery varieties, in particular, are believed to be formed near the surface of the earth; and they have a greater density than the flaky varieties, and fall more rapidly, and enclose a much smaller volume of gases within their cells and interstices, and possess much less power to act usefully upon the soil and upon vegetation. The flaky and spicular varieties are very numerous, and, in most instances, have very beautiful crystalline forms. Some are lamellar stelliform crystals; some, lamellar regular hexagons; some, lamellar aggregations of hexagons; some, lamellar hexagons with projecting radii or salient angles; some, spheres or central lamellar plates with spinous processes; some, six-sided prisms; some, hexagonal pyramids; and some, spiculæ with one or both extremities fixed to the centre of a lamellar plate. The six-sided prisms are hard and firm and small, and appear to be formed at much higher elevations than the other kinds; they constitute the chief bulk of the snow of very lofty alpine regions, and are there lifted and whirled and tossed by the winds in a similar manner to the light sands of an arid desert; and they are commonly accompanied in Britain with some of the lamellar varieties, which are believed to intercept them and mix with them in the lower part of their descent. The wheeled and stellate and spinose and compoundly hexagonal varieties constitute the largest flakes and the softest snowy masses, and fall in calm weather, in low districts, and with a slow and sluggish motion. Flakes which are nine times less dense, or nine times more expanded then water, fall, on the average, three times less slowly; and the largest flakes are commonly formed in a frost so mild as to make the crystals soft and humid, and to allow them to cohere somewhat in the manner of the rays of feathers. All flaky snow, as soon as it has fallen, begins to consolidate into increasingly denser conditions; and it owes both this power of self-condensation and the capacity of great cohesion under mechanical pressure to the acicular texture of its crystals, and to the presence of a certain degree of enclosed and coherent moisture which afterwards freezes. Sheets of snow on the ground are well known to reflect beautiful pink and blue tints under certain angles of sunshine, and to fling back so much light as to be painful to the eyes by day and to guide the traveller in the absence of moonshine at night. Snow, especially when newly fallen, contains a comparatively large impregnation of carbonic acid, ammonia, and other atmospheric gases; and yet, when caught in falling, or when lifted without permitting any possibility of contamination from the soil or from smokes or exhalations, it yields as pure water as mountain rain, —the purest which can be obtained from natural sources.

Snow is an exceedingly reluctant conductor of heat; and, when forming a layer of two or three inches, or even less, upon the soil, it prevents the internal heat of the earth from radiating into the atmosphere, and preserves the surface of the land from congelation by subsequent frost; and it therefore ameliorates the soil in winter, protects the life of the natural grasses and herbage plants during the long and rigorous frosts of high latitudes, shelters the cereal grasses and other field-plants of Britain so as to keep them safe in winter and make them rise vigorously in

spring, and occasions a continual flow of water in the form of perennial springs from beneath the perpetually frozen summits and shoulders of alpine mountains.

The sowing of the seeds of many kinds of greenhouse plants in snow, such as those of the heath, the rhodora, the cactus, the leguminous, and the gourd orders, has been found, in somewhat recent experiments on the Continent, to promote germination. The manner of sowing is to fill the pots to a suitable height with the kind of soil proper for each species, to put a layer of snow on the top of the soil, to sow the seed on this, to put another layer of snow over the seed, to set the pots thus sown in a glass-covered box, to place the box in a house at a temperature of about 59° or 60° Fahrenheit, and, as soon as the snow melts or the germ appears, according to the nature of the species, to lay on a sprinkling of sandy earth. The germination is said to be both surer and more rapid than in the ordinary methods of sowing. "It appears to me," says Liebig, "that the loose formation of the snow, which allows of an uninterrupted admission of oxygen, the exclusion of those foreign agents which are always found in a soil that contains corrupted vegetable matter, and finally, the volatile alkali of the snow—all these causes combined effect the remarkable appearance of germination in this process." Another physiologist takes a similar view of the matter, and suggests the two following additional explanations:—"1. When the seed is in the snow, the temperature cannot be far from the freezing point, as long as there is snow there; the melted snow, provided it is not warm, does not draw any matter from the seed which is necessary for its vitality, therefore, it remains the same. 2. The melted snow only moistens the surface of the seed, without submerging it, and easily penetrates the cells of the seeds by means of the capillary tubes, from which the air must escape; if the seed is too moist, the excess of fluidity does not produce a proportionate softness of the seed, as the air that is contained in the seed cannot so easily escape to give place to the moisture."

SNOWBALL-TREE. See GUELDER ROSE.

SNOWBERRY, — botanically *Chiococca*. A small genus of exotic plants of the madder family. The racemose species, *C. racemosa*, is a white-flowered, ornamental, evergreen, winter-blooming shrub, of about 6 feet in height, and was introduced to the hothouse collections of Britain, upwards of a century ago, from Jamaica. —The serpent-expelling species, *C. anguifuga*, is a white-flowered, medicinal, evergreen, summer-blooming shrub, of about 3 feet in height; and was introduced to Britain about 24 years ago from Brazil.

SNOWDROP, — botanically *Galanthus*. A small genus of hardy, ornamental, bulbous-rooted plants, of the amaryllis order. The common species, *G. nivalis*, grows wild in the meadows, orchards, hedge-sides, and river-banks of many parts of Britain; and is a great and universal favourite as a winter-blooming or early spring-blooming ornament of all sorts of open-ground flower gardens. It comprises three varieties,—the single, the semi-double, and the double. Its bulb resembles that of a narcissus, but is much smaller; its leaves rise from the crown of the bulb, and are erect, obtuse, keeled, and glaucous; its flower-stalk ascends from the midst of the leaves, and is slender, drooping, and about 4 or 6 inches high; and its flower is solitary, white, scentless, and beautiful. This plant thrives in almost any soil, and multiplies exceedingly by bulbous offsets, and requires scarcely any culture; and though inconspicuous and paltry when planted singly, it makes a fine appearance, and contrasts most sumptuously with the general wintriness of the garden, when planted in close groups of twenty bulbs or upwards in each group. It prospers well under trees or hedges; and is therefore suitable for wood-walks and wilderness quarters. The bulbs may be taken up in the latter part of June, when the leaves decay, and may be kept out of the ground till the end of August; but they must not be removed oftener than every third year.—The plaited snowdrop, *G. plicatus*, was introduced to Britain about 30 years ago from the Crimea; and is similar in height and habit and general appearance to the common species.

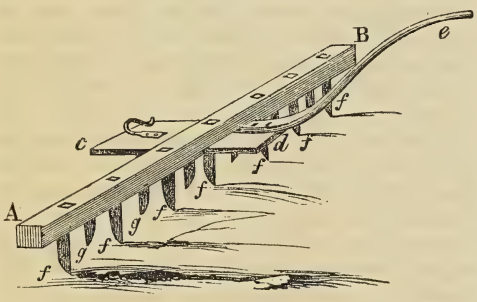
SNOWDROP-TREE,—botanically *Halesia*. A small genus of hardy, ornamental, white-flowered, deciduous, North American shrubs, of the storax family. Three species, the two-winged, the small-flowered, and the four-winged, respectively about 6, 8, and 10 feet high, have been introduced to the shrubberies of Britain; and all bloom in the advanced part of spring, and love a soil of peaty loam, and are propagated from layers.—The name snowdrop-tree is sometimes given also to the chionanthus genus. See the article FRINGE-TREE.

SNOWFLAKE, — botanically *Leucojum*. A genus of hardy, ornamental, bulbous-rooted plants, of the amaryllis order. The summer species, *L. æstivum*, grows wild in the moist meadows and marshy river banks of some parts of England, and has a height of from 15 to 20 inches, and blooms in April and May; and the spring species, *L. vernum*, was introduced to Britain from Germany toward the close of the 16th century, and has a height of about 8 or 10 inches, and blooms from January till March,—but comprises a later blooming variety from the Carpathian Mountains, and an abundantly flowering variety which originated in gardens; and both species have white flowers very similar to those of the snowdrop, and were formerly known among florists under the name of tall snowdrops, —and they love a soil of sandy loam, and are propagated, in the same sort of way as daffodils and narcissi, from bulbous offsets.

SNOW-HARROW AND SNOW-PLOUGH. Implements for making such tracts through snow on sheep pastures as will facilitate the melting of the snow, and enable sheep to move about with ease in search of their food. They are often of great use in upland districts, both during protracted snow-storms in winter, and after falls of snow subsequent to the commencement of the lambing season. A snow-harrow and a mountain snow-plough which were constructed by J. Stewart Hepburn, Esq. of Colquhalzie, and which were honoured with the Highland Society's silver medal, and are described in their Transactions, seem to be perfectly efficient, and at the same time possess the recommendation of comparative simplicity.

"The snow-harrow," says Mr. Hepburn, "consists of a bar or head A B, Fig. 1, 4½ inches square, and 6 feet long, in the middle of which, on the under side, a piece of 1¼-inch plank *c d*, 3 feet long, is sunk flush transversely, for the

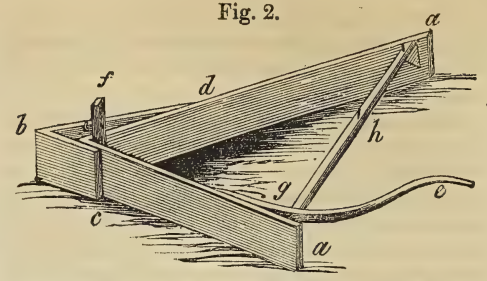
Fig. 1.



attachment of the draught-hook, *c*, and the stilt, *e*, and to steady the motion of the implement. In this head are fixed, by screw-nuts, at intervals of 10 inches, 7 cutters *f f*, &c., 9 inches long, and 1⅜ broad, sabre-shaped, with their points turned backwards, so as to be less readily arrested by obstacles on the surface of the ground. Between these are fixed 6 short cutters *g g*, &c., 3 inches long, having their points turned forwards. This implement dragged by one horse, rode by a boy, and the stilt held by a man behind, cuts the frozen snow into stripes 5 or 6 inches broad, which are easily pulverized by the feet of the sheep, or divided by the snow-plough."

"The severity of the winter of 1837-8 in mountain sheep-pastures," continues Mr. Hepburn, "led me to attempt to adapt the snow-plough, with or without the aid of the snow-harrow, for being applied in such situations. To enable the plough to clear tracks for the sheep along the steep hill-sides, it is necessary it should be made to throw the snow wholly to the lower side. To effect this, I caused to be fitted to the plough, *a a*, Fig. 2—the body of which forms an isosceles triangle, whose sides are 7½ feet, and its base 6 feet in length, the depth of the sides being 15 inches—a shifting head, *b c d*, with unequal sides; one, *b c*, being 18 inches; the other, *b d*, 30 inches long, fixed by iron pins

Fig. 2.



passing through 2 pairs of eyes, as seen at *c*, attached to the head and to the sides of the plough respectively, so as to bring the point of the attached head of the plough nearly into the line of its upper side, or that next the hill. The stilt, *e*, at the same time, was made moveable by a hinge-joint at its anterior extremity, fixed to the bottom of the head frame-post *f*, so as to be capable of being fixed to the cross-bar or stretcher, *g a*, either in the line bisecting the angle, as at *h* (which is the position for level ground), or in the line, alternately, of either of the sides, *b a* or *b g*, when to be used on a declivity. The draught-chain is fixed, not to the shifting head, but to the upright frame-post *f*, in the nose of the plough which rises 10 or 12 inches above the mould-boards. When the plough, so constructed, is to be worked along a declivity, with the left hand towards the hill, the shorter limb of the shifting head is fixed on the left side of the plough, near the point; and the longer limb, on the right side, towards the middle; and, the stilt being fixed on the left extremity of the cross-bar, nearly in a line with the temporary point, the plough is necessarily drawn in the direction of its left side, so as to throw the snow wholly to the right down the hill. When the plough is to return across the declivity with its right side to the hill, the moveable head is detached by drawing out the linch pins, is turned upside down, and fixed in a reverse position; the shorter limb being attached to the right side, and the longer to the left side of the plough, while the stilt is brought to the right extremity, *a*, of the cross-bar. The plough is then drawn in the direction of the right side, and the snow is thrown wholly to the left, now the lower side. Should the lower side of the plough show a tendency to rise, it may either be held down by a second moveable stilt, fixed to the middle, *h*, of the cross-bar, or a block of wood, or other ballast weight, may be placed on that side of the plough."

SNOW-THISTLE. See ANDRYALA.

SOAP. A compound resulting from the combination of an oil or a fat with an alkali or an alkaline earth. See the article OIL. It was invented by the Gauls at a period prior to historical record; and has long been a common article of manufacture, in many ways, of many varieties, in many lands. It is usually made of the cheapest fats and crudest alkalies in rude countries,—of animal fats and coarse alkalies, with various admixtures,

in Britain, — and of vegetable oils and refined alkalies, with sometimes modifying substances, in some parts of the south of Europe. Hard soap owes its distinctive characters to soda; soft soap, to potash; white soap, to comparatively pure tallow; yellow or brown soap, to a mixture of tallow and resin; and mottled soap, to the dispersion of ley throughout it in the last stage of its manufacture, or to the admixture of sulphate of iron, oxide of manganese, and other colouring substances. The desirable properties and the detergent uses of all common soaps are so universally known as not to require any remark. Well-made, hard soap, fit for internal administration as a medicine, should be made of olive oil or almond oil and soda; and is generally imported from Spain and Italy and the South of France; and has a white colour, a firm consistence, a marble-like surface, an alkalescent taste, and very little odour,—makes an opaque milky solution with water,—and is decomposed by all the acids, by acidulous salts, by all the earths, and by most of the metallic salts. It is used, in human pharmacy, as a lithontriptic, a mild aperient, a diuretic, and an antidote to metallic poisons; and in veterinary pharmacy, as a diuretic, and sometimes, though quite improperly, as an ingredient in physic balls. Soap of various kinds and in various ways is also used externally as a remedy for tumefactions, sprains, and bruises.

SOAPBERRY,—botanically *Sapindus*. A genus of ornamental, tropical, thalamiflorous, evergreen, ligneous plants, constituting the type of the natural order Sapindaceæ. The petals of this order have either an additional lobe inside or a tuft of hairs instead; the flowers of most are white and grow in bunches; and the leaves of nearly all are compound. A few of the species are twining herbs; but most are shrubs or trees; and nearly all are natives of the tropical or subtropical regions of the old world. The entire fruit of a few is deliciously esculent; and parts of the fruit of one or two others is also excellent eating. One hardy species, nearly twenty greenhouse species, and about eighty hothouse species have been introduced to Britain, and are distributed among three tribes and about twenty genera.

The soapberry genus comprises about a dozen of the introduced species, and nearly as many more known unintroduced species. All the introduced species are hothouse, evergreen small trees or tall shrubs, varying in natural height from 10 to 30 feet, carrying either white or herbaceous-coloured flowers, and, with some exceptions, loving a soil of peaty loam and propagable from cuttings.—The common species, *Sapindus saponaria*, was introduced about 250 years ago, and is a native of the West Indies. Its stem naturally attains a height of from 20 to 30 feet, and sends out many branches toward the top; its leaves are pinnate, and comprise each a midrib with a leafy border and from three to five pairs of leaflets; its leaflets are pale green, pretty stiff, from 3 to 4 inches long, pointed at both ends, and about 1¼ inch broad in the middle; its flowers come out in loose spikes at the ends of the branches, and are small, white, and inconspicuous; and its fruit are oval berries, about as large as middle-sized cherries, growing singly or in twos or threes or fours, each comprising a saponaceous skin and an enclosed, hard nut. The skin of the fruit is used in America for washing linen, but, when employed often, is very apt to burn and destroy it; and the nuts are very smooth and of a shining black colour, and were formerly imported to England, and manufactured into buttons, which were sometimes tipped with silver, and always very durable.—The emarginated soapberry, *Sapindus emarginatus*, was introduced about 26 years ago, and is a native of India. It has naturally a height of about 15 feet. The skin of its fruit is used by the Hindoos for the same purposes as soap, and prescribed by their physicians as a remedy for humoral asthma.—The rusty soapberry, *Sapindus rubiginosus*, is also a native of India, and has naturally a height of about 15 or 20 feet; and its timber is straight, strong, and durable, and is found very useful for a great variety of purposes.

SOAPER'S WASTE. The refuse of soap manufactories. It varies in composition according to the kind of soap from which it comes, and the qualities and condition of the alkali employed; but, in all its varieties, it acts as a powerful fertilizer. One specimen or coarse kind of it is stated, in a crudely reported analysis, to comprise 57 per cent. of mild calx, 11 of magnesia, 6 of argil, and 21 of silex; but such a kind as this, which comes from soap made with lime and the crude varieties of kelp and barilla, is less valuable than kinds from soap made with good kelp and barilla; and these latter, again, are less valuable than kinds from good or best common white soaps. "Soaper's waste," says Donaldson, "has been applied on almost every description of soil, and generally with good success. On cold wet soils, on sour meadows, and on moss, the effects have been great with 60 bushels to an acre; while in some instances, the quantity applied to an acre has been as much as 40 tons, and the average allowance may be stated at 150 bushels. The hot caustic quality will be harmless on wet strong soils; on all light lands, the safer mode of application will be by mixing the soap with four times the bulk of good earth, which will make a fine compost for grass-lands and young crops. The caustic quality of such substances requires correction, which is well accomplished by exposure, and by mixing with cool materials in a greater quantity. Great results have been published as having been derived from using soaper's waste; and in experiments with other manures the unmixed substance seems to have yielded most produce, while in another instance an application to wheat showed no per-

ceptible difference. A waggon load is said to be equal to five loads of rotten dung, and more confidently that one load of soap waste, with 5 of dung, would be more valuable than 10 of dung, both in effect and in duration. The first substance will cover less ground at the same rate of application, and if laid on the same extent of space, one would think that the superior or equal quality has much to contend against,—in one case, more extent of ground,—and in the latter, the effects of nearly twice the quantity of the substance of which it is chiefly composed."

SOAPWORT,—botanically *Saponaria*. A genus of ornamental herbaceous plants of the carnation family. The officinal species, *S. officinalis*, grows wild in meadows, under hedges, on river banks, and in similar situations in many parts of England. Its root is perennial, creeping, spreading, ramose, and rather fleshy, and soon occupies a large space of ground; its stems are jointed, erect, cylindrical, purplish, leafy, and about 18 inches high; its leaves are opposite, ovate-lanceolate, smooth, pale green, and about 3 inches long and $1\frac{1}{2}$ inch broad; its flowers come out in dense panicles from the wings of the leaves, and are large, handsome, and of a flesh or pale pink colour, and emit an oppressively sweet odour, and bloom from July till October; and its capsules are oval and one-celled, and are filled with many small seeds. A decoction of this plant has been used in some countries as a substitute for soap, and is well capable of cleansing woollen fabrics; and the leaves were formerly used in medicine, and are accounted opening, attenuating, and somewhat sudorific. A variety with double flowers, *S. o. plena*, has long been known in the flower-garden; but it spreads so rapidly and far, that it ought not to have a place among better flowering-plants.—Four or five perennial-rooted species, one biennial, and seven or eight annuals, have been introduced to Britain, principally from Continental Europe and the Levant; and all are hardy, most have either pink or red flowers, some are truly beautiful, and well worthy of a place in the flower border, and the majority love a soil of sandy peat, but will thrive in all common light garden soils. The basil-like species, *S. ocymoides*,—a native of France, a low evergreen trailer, with handsome red flowers, blooming from May till July—is well adapted for rock-work.

SODA. The protoxide of sodium. It is obtainable in large quantities from sea-water, and occurs profusely, though somewhat mixedly or impurely, as an efflorescence on the marshes and lake-banks of some hot countries, and is an important ingredient in soils, and can be manufactured from some large deposits of the saliferous sandstone formation,—and, for all these reasons, as well as for the sake of distinction from potash and ammonia, it has been not inappropriately called the mineral alkali; but it is also an important constituent of many plants,—and, in point of fact, was long obtained for commercial and manufacturing and economical and medicinal purposes mainly through the medium of kelp, from marine algæ, and through the medium of barilla from the plant called *Salsola soda* and from other plants of the goosefoot order. See the articles Kelp, Barilla, Alkalies, Ashes, Salts, and Goosefoot; and see also the articles Nitrates, Natron, and Salt (Common).

Sodium is an elementary substance of a metallic nature; and was discovered in 1807 by Sir Humphrey Davy. It does not naturally occur in a simple state; but may easily be obtained from its natural compounds by means of galvanism, or by similar processes to those used for obtaining potassium from the salts of potash. It has a colour similar to that of silver, and a strong metallic lustre, and a specific gravity of 0·972; it is compressible by the fingers at common temperatures, and melts at 200° Fahrenheit, and rises into vapour at a red heat; and when thrown upon water, it causes a violent effervescence, emits a hissing noise, and rapidly combines with oxygen so as to form soda. The peroxide of sodium, consisting of two equivalents of sodium and three of oxygen, may be artificially formed by heating sodium to redness in excess of pure oxygen; but it is of small economical importance, and is resolvable by water into soda and oxygen.

Soda, or protoxide of sodium, is obtained in purity by burning sodium in dry atmospheric air. It consists of one equivalent of sodium and one equivalent of oxygen; and is a grey white solid, difficult of fusion. It forms with water, equivalent to equivalent, a solid hydrate; and this is soluble in water and alcohol, easily fusible by heat, very caustic, and exceedingly analogous in all its chemical relations to potash. All the salts of soda are soluble in water, and are incapable of being precipitated thence by any reagent; all, on being exposed by means of platinum wire to the blow-pipe flame, communicate to it a rich yellow colour; and soda itself combines with sulphuric acid to form a salt which is easily recognised by its taste and form to be Glauber's salt; and by these three characters is soda chemically and readily distinguishable from other alkaline bases.

The common uses of soda are mentioned in the articles Kelp and Barilla; and two of the most important salts of it are noticed in the articles Glauber's Salt and Nitrates.—The carbonate of soda is prepared by a purifying process from barilla; and forms into large, transparent, octahedronal crystals with a rhombic base; and has a mild alkalescent taste; and is used in medicine as an antacid and a deobstruent. Its crystals contain a large proportion of water of crystallization; and when exposed to a dry atmosphere, they effloresce and crumble into a white opaque powder.—The bicarbonate is prepared from the carbonate; and forms into very white

minute crystals, free from alkaline taste ; and is used medicinally for the same purposes as the carbonate, and for making extemporaneous effervescing draughts with tartaric and citric acids; but has no medicinal superiority over the carbonate, except that it is less nauseous.—The phosphate is prepared from the carbonate together with bones and sulphuric acid ; and forms into large, transparent, regular, oblique, rhombic prisms ; and has a purely saline taste similar to that of common salt ; and is used in medicine as a mild cathartic.—The acetate is prepared from the carbonate together with distilled vinegar ; and forms into solid striated oblique rhombic prisms ; and requires to be kept in closely-stopped bottles ; and has a sharp bitter taste ; and is used in medicine as a diuretic.

SOD-BURNING. See Paring and Burning.

SOFT GRASS. See Holcus.

SOIL. The covering or thin uppermost stratum of the earth's crust. It is understood by general observers as simply the ground, without any reference to either its depth or constitution or uses ; by geologists, as the superficial alluvial or diluvial deposit of the earth, to whatever depth it possesses homogeneity of character ; by botanists, as the portion of the earth's surface which supports vegetation, in all its classes and kinds, whether naturally or with the aid of culture ; and by farmers and gardeners, as the portion of the earth's surface which is stirred by the plough or the spade or otherwise subjected to tillage. The first of these four senses of soil is entirely popular, and does not recognise any subsoil, and is totally unsuited to any useful purpose, either scientific or technical ; the second refers solely to manner of formation and to mineral constituency, and recognises subsoil only in the sense of a substratum of different geognostic character from the soil, and therefore lying at depths varying from less than an inch to upwards of a thousand feet ; the third refers to the portion of surface, whether thin or thick, which, in the course of ages, has become impregnated with organic remains by the growth and decay of successive races of plants, and by either natural or artificial processes of manuring,—and it recognises as subsoil whatever lies immediately below this vegetation-supporting stratum ; and the fourth refers to any uniform depth of surface which is statedly or occasionally worked by tillage, whether only an inch or two by the most scratchy methods of barbarous husbandry, or from eighteen to thirty-six inches by the most elaborate methods of spade-trenching, plough-trenching, and subsoil-ploughing,—and it recognises as subsoil all the matter from the plane of the bottom of this stratum down to any depth, small or great, which can affect the circulation of moisture, air, and heat. Our work, of course, uses the word principally in the fourth sense,—in that of farmers and gardeners ; yet it also uses it occasionally in the third sense, or that of botanists,—especially in so far as this sense applies to cultivated land, and is quite or nearly synonymous with mould. The soil, in the farmer's sense, is sometimes of the same depth as the mould,—sometimes not so deep,—and sometimes deeper ; and it may rest on a subsoil either similar to itself or dissimilar, either homogeneous or heterogeneous, either workable or rocky, either deep or shallow ; and, with the exception of the characters resulting from profuse organic remains, tillage, and high atmospheric action, the subsoil may be as various in constitution and condition as the soil. Throughout the great majority of upland pastures, of rocky wastes, and of silicious, arid, uncultivated grounds, the soil is strictly coincident with the mould, and varies in depth from a shallowness scarcely appreciable to not more than a few inches ; and throughout the great majority of good arable lands, it either has naturally a great depth of all the requisites of fertility, or is capable of being artificially deepened to any degree which the demands of cultivation can require. In all the latter lands, too, however homogeneous any portion of it originally was with the subsoil, it has been so changed by artificial pulverization, by artificial supplies of organic matter, by artificial turnings of it to the action of the air and weather, and by the several other artificial accidents of cultivation, that it has now a finer texture, a darker colour, a richer impregnation of humus and salts, and altogether a different appearance and character.

The Formation of Soils.—The formation of the shallow soils of hills and mountains and rocky plains has rarely received aid from man, and has generally consisted in the disintegration of the rocky surfaces immediately below them, and in the natural progress and deposits of spontaneous vegetation. "The influence of heat and moisture tends to facilitate the gradual disintegration of even the hardest rocks ; and as soon as the smallest portion of loose matter or earth is formed on their surface, traces of an obscure vegetation begin to manifest themselves. Lichens of various kinds spring up, one generation succeeding another, until of their decayed and partially decomposed fragments, a soil is prepared for the reception of the mosses. These in their turn decay, and their decomposition affords a certain quantity of organic matter, which mixes with the disintegrated portions of the rocks ; and in this improved soil other kinds of plants are capable of subsisting. Meanwhile, the atmosphere still exerting its influence on the surface of the rocks, and the roots of the plants penetrating into their fissures, an augmentation to the mass of the soil is preparing, so that by such slow and gradual means a soil is formed, in which even forest trees can fix their roots. Thus that which was originally a bleak and ominous mass of rock, became capable of supporting successively the various tribes of plants, and fitted to reward the labours of the cultivator."

A large proportion of good deep arable soils, comprising the alluvial and the diluvial, were originally formed in the manner described in the articles ALLUVIUM and DILUVIUM; all moss-lands and peat soils were originally formed in the manner described in the article BOG; some arable lands were originally formed in a manner intermediate between shallow hill-soils and alluviums, having acquired their mineral constituents partly from disintegrations of the surfaces immediately below them and partly from the washed-down debris of the neighbouring declivities; and almost all cultivated soils, of whatever original formation, have undergone modifications first from the natural processes of spontaneous vegetation, next from the artificial processes of tillage and culture, and, concurrently with both of these, from the chemical action of air, heat, light, moisture, and the weather. See the article ALKALIES.

The Composition of Soils.—The composition of some soils is very largely silicious,—of others, very largely aluminous,—of others, very largely calcareous,—of others, very mixedly mineral,—and of others, chiefly or almost solely humous; and this wide diversity, with all its intermediate gradations, together with differences of mechanical condition, of subsoil, of situation, of climate, and of artificial or georgical character, gives rise to the classification of soils of which we must treat in the next section. But we speak here of the composition of soils in the aggregate; and we may represent them as comprising three great classes of bodies,—earths, salts, and organic matters,—and as, at the same time, involving a necessary and constant permeation by heat, moisture, and atmospheric gases. The earths, the salts, and the organic matters, are discussed separately and in a general way in respectively the articles EARTH, SALTS, and HUMUS; and all are also discussed, collectively, in their relations to the soil, in the articles MANURE and FOOD OF PLANTS. The three principal earths are discussed separately in the articles SILICA, ALUMINA, and LIME; and the forms or combinations in which they most commonly exist are discussed also in the articles SAND, CLAY, CHALK, and LOAM. A less common earth is noticed in the article MAGNESIA; and another mineral constituent of soil, the rust or oxide of iron, not properly an earth, and comparatively very small in amount, but plentiful enough to give much of it a reddish colour, and sometimes existing under such conditions as to act like a poison on plants, is noticed in the article IRON. The most important salts, whether as to bulk, as to economy within the soil, or as to nutritional connexion with plants, are discussed in the articles AMMONIA, NITRATES, PHOSPHATES, SILICATES, CARBONATES, SULPHATES, and ALKALIES. And the principal organic matters, whether those which accumulate by the decay of a long succession of different sorts of vegetables, or those which become soon abstracted from a virgin soil by constant cultivation, and require to be periodically supplied in the form of manure in order to maintain fertility, are discussed in the articles HUMUS, MOULD, EXCREMENTS, ANIMAL MANURES, and FARM-YARD MANURE. Connected views of the entire constitution of soils in their relations to vegetation and cropping, and of the slow mutations which they undergo during the processes of cultivation, are given also in the articles MANURE, AGRICULTURAL CHEMISTRY, and ROTATION OF CROPS.

All the constituents of soil exist as compounds, and perform their offices as compounds, and are obtained in analyses as compounds. The earths, for the most part, are oxides, or combinations of metallic bases with oxygen; the salts, for the most part, are double compounds, or combinations of either alkalies or alkaline earths with acids; and the organic matters are animal and vegetable principles in a decomposing state,—naturally very compound, and always passing by decay into other and less compound forms. The silica in soils commonly exists in mechanical combination, or intimate commixture, with alumina or oxide of iron, or with alumina, lime, magnesia, and oxide of iron, forming sand and gravel of different degrees of fineness. Most of the lime exists naturally in the state of carbonate,—most frequently in an impalpable form, but sometimes in the state of calcareous sand; and even when added artificially in the state of mere earth or oxide, it exists as a hydrate, and gradually passes into the state of a carbonate. The alumina commonly exists in an impalpable form, and in mechanical combination with minutely comminuted or very finely pulverized silica, lime, and magnesia, constituting the various kinds of clays, argillaceous earths, and clayey loams. The magnesia, when not combined with unreduced portions of gravel and sand, occurs in a fine powder in the state of carbonate. The salts occur variously in combination with the mineral matters, in combination with the organic matters, and in evolution or progressive formation from the elements or principles let loose by the gradual decomposition of other bodies. The organic matters occur in different states and stages of decomposition, from the slightest degree of appreciable decay to an ultimate resolution of all their principles into powders and gases, and are therefore variously compact, fibrous, pulverulent, pulpy, and aeriform.

All soils originally derived all their mineral constituents, directly or indirectly, from the disintegration of rocks; and they owe their distinctive mineral characters,—the predominance of one earth, the alternations of two or more, or the prevailing intermixture of several,—to the character and distribution of the rocks which yielded them. The several rocks were dissevered into parts and ground into powder of different degrees of smallness by the action of air and water and weather; solutions of some of their

saline constituents were formed in water, and diffused through the disintegrated masses, and deprived of their impregnations by the fragments and granules; and larger or smaller quantities of vegetable and animal remains, either produced on the spot, or brought down from higher grounds by rains and streams, settled down upon the surface, and became intermixed with the moistened minerals. Rocks of widely different constitution sometimes occur in close juxtaposition to one another within the upper regions of the same river-basin,—and then they give rise to a very diversified soil upon the hills, and to a very mixed alluvium upon the plains; but they sometimes occur also far asunder from one another, each kind or class forming the floor and walls of an entire basin,—and then they give rise to somewhat uniform soils upon both hill and plain,—the silicious rocks to sand and gravel, the aluminous ones to clay, and the calcareous ones to chalk or to limestone gravel.

Both the mixed soils from any given group or segregation of rocks, and the uniform soils from any one species or class of rock, are originally the same in all parts of the world; for so long as rocks of any one kind or class or grouping occur as sources of either detritus or alluvium, no matter where, their constituents are always the same, and must necessarily yield by disintegration the same sort of fragments and powder. Yet soils originally the same, or still minerally the same, differ widely and in many gradations from one another in consequence of mechanical condition, subsoil, situation, climate, and cultivation. The coarseness of granules or fragments, even in cases where the material is intrinsically suited to evolve the highest fertility, may be so excessive in itself, and so unrelieved by the presence of any finely divided matter as to render the soil absolutely barren. A soil of any kind immediately incumbent on rock or sand, especially in such wet districts as those of the west coast of Britain and the greater part of Ireland, may be comparatively dry, open, and fertile, while exactly the same soil incumbent on clay or marl or on an impervious compound of clay and sand may be marshy, close, and almost worthless. Any soil in a warm, dry country, is more absorbent of moisture, has a freer internal circulation, and makes richer accumulations of salts, alumina, and organic remains, than the same soil in a cold wet country. A soil upon a declivity makes better natural improvements, and is less exposed to natural deteriorating influences, than a soil upon a level; and one upon a declivity looking to the sun is superior in these respects, to one upon a declivity with any other exposure. Soils in wet, cold climates, with comparatively slow vegetable growth and comparatively little evaporation are liable to become choked with aquatic cryptogams, and even converted into sheer moors or bogs, while soils of the same kind in dry hot climates, with luxuriant vegetable growth and great and rapid evaporation, remain sound and open, and generally possess a constant, increasing, natural capacity of improvement. The ultimate composition of soils, therefore, is, in a very considerable degree, determined by the action or influence of subsoil, situation, and climate; and so very greatly is it affected by cultivation—in the processes of pulverization, of trenching, of fallowing, of cropping, and especially of manuring—that, in the case of many lands which have been specially reclaimed or have been long in tillage, the original character of it cannot be traced.

Classification of Soils.—A good classification of soils, together with a simple, fixed, comprehensive, and well-defined nomenclature, is essential for enabling farmers to form comparative estimates of the different soils of their own farm or district, to trace the resemblances between these and the soils of other districts, to decide how far any peculiar treatment of one soil may be profitably imitated upon another, to determine the kind and amount of mineral admixture which any soil may require for its proper textural amelioration, and especially to reap fair or full benefit, or even to obtain clear ideas or intelligible hints, from the multitudes of reports of valuable experiments on manures, methods of reclamation, improvements in culture, and other similar subjects, which abound in the agricultural periodicals of the day. The best which has yet been published is Schübler's of Germany, slightly altered by Dr. Daubeny, and founded entirely on the relative proportions of the four chief constituents of all soils,—clay, sand, lime, and humus. "In this," says Dr. Daubeny, "we begin with those soils which contain little or no calcareous matter—at the outside, not so much as 5 per cent. of the whole mass. These, supposing them to possess 50 per cent. of clay, are placed under the head of argillaceous soils, and are distinguished into two orders, the first wholly destitute of lime, the second containing less than 5 per cent. of that earth. Each of these orders is then subdivided into three species, distinguished as rich, poor, and intermediate, according to the proportion of humus or vegetable mould present in them. If the amount of this ingredient be not more than $\frac{1}{2}$ per cent. the soils are called poor, as the fertility of a soil is in all cases greatly influenced by the proportion of this ingredient; if it varies from 0·5 to 1·5 per cent., it is called intermediate; if from 1·5 to 5·0 per cent., it is distinguished as rich. The second class of soils comprehends those which contain from 30 to 50 per cent. of clay, and is denominated loamy. These likewise are divided into two orders, the one with, the other without lime; and again into three species, according to the proportion of vegetable mould present in them. The third class embraces those soils which contain not more than 30 nor less than 20 per cent. of clay. They are called sandy

loams, and are subdivided into orders and species, on the same principle as before. In the next or fourth class, under the denomination of loamy lands, are ranged those soils which contain from 10 to 20 per cent. of clay,—the remainder, with the exception of the small per centage of limestone and humus they may contain, consisting of sand. The fifth class, designated as sandy, includes all those soils in which the proportion of clay does not exceed 10 per cent.; and here again the same subdivisions are adopted. Hitherto, the amount of calcareous matter present is not supposed to exceed 5 per cent.; but in the next class, that of marly soils, the above ingredient ranges in a proportion varying from 5 to 20 per cent. of the whole. Marly soils are to be distinguished into five orders, of which the first, called argillaceous, contains about 50 per cent. of clay; the second, loamy, from 30 to 50; the third, sandy-loamy, from 20 to 30; the fourth, loamy-sandy, from 10 to 20; and the fifth is distinguished by the larger proportion of *humus*, which exceeds in quantity 5 per cent. of the whole, and is therefore denoted as *humous marl;* which last is divided into three species—viz., argillaceous, which contains about 50 per cent. of clay; loamy, which contains from 30 to 50 per cent.; and sandy, possessing from 20 to 30 per cent. of the same ingredient. We next arrive at that class of soils which contains more than 20 per cent. of carbonate of lime, and which is therefore distinguished as calcareous. These are subdivided according to the proportion of clay they may contain: when this earth exists in the proportion of more than 50 per cent., they are to be called argillaceous; when it is from 30 to 50, loamy; when from 20 to 30, they are said to belong to the sandy loams of the calcareous class; when from 10 to 20, to the loamy sands; and when either destitute of clay altogether, or containing at most only 10 per cent. of it, they are called sandy. Lastly, a calcareous soil which contains more than 5 per cent. of vegetable mould belongs to the sixth order, that of humous calcareous soils, of which there are three species—namely, the argillaceous, the loamy, and the sandy, characterized as before, by the larger or smaller proportion of clay present in them. The last class, that of humous soils, is distinguished in the first place, into three orders. The first consists of soluble mild humus—that is, of that description of vegetable mould which is in a fit condition to nourish the plants which grow in it; the second, of acid humus, namely, containing a free acid, which by its presence is highly destructive to most kinds of vegetation; a third order consists of fibrous vegetable matter, such as peat, which, though not acid, is yet in a condition little fitted for imparting nourishment to plants. These orders are again subdivided into argillaceous, loamy, and sandy, according to the proportion of clay present in them; and lastly distinguished into two species, the one containing, the other destitute of, calcareous matter."

The following table can readily be understood and used by any farmer, and ought to put an end to the loose and ambiguous phraseology which prevails in the popular nomenclature of soils, and might be of great service to the agricultural community till a better classification shall be made. But it is defective, as to the aids it should afford both to experimenting and to current farming, in not noticing the gradations of sand and gravel with respect to the size of their fragments and granules,—in not noticing the condition of the lime, whether powdery and artificially supplied, or in the state of natural chalk, or in the state of limestone gravel, or in the state of gypsum,—in not noticing the presence and proportions of the rarer and most fluctuating ingredients which play a main part in the nutrition of crops, such as the alkalies, the phosphates, and the nitrates, —and in not noticing the mighty modifications of the several soils, or the wide varieties in their existing fertility, which result from subsoil, situation, climate, drainage, cleanness, and agricultural treatment.

Names of the Different Descriptions of Soil.			Proportion in every 100 Parts.			Agricultural Designations and General Relations with Reference to their Produce.*
Classes.	Orders.	Species.	Clay.	Lime.	Humus.	
1. Argillaceous Soils. — Above 50 per cent. of Clay. More than 5 per cent. of Lime.	Without Lime.	Poor	Above 50	0	0 to 0·5	*Land for Wheat and Spelt.* The calcareous kinds not too rich in clay, and not too poor in sand and humus, give good returns. Wheat, spelt, barley, rape, beans, flax, and clover, flourish in it especially. Those poor in humus are still suited for oats.
		Interm.	„ 50	0	0·5 to 1·5	
		Rich	„ 50	0	1·5 to 5·0	
	With Lime.	Poor	Above 50	0·5 to 5·0	0 to 0·5	
		Interm.	„ 50	0·5 to 5·0	0·5 to 1·5	
		Rich	„ 50	0·5 to 5·0	1·5 to 5·0	
2. Loamy Soils. — Not more than 50 nor less than 30 per cent. of Clay. Not more than 5 of Lime.	Without Lime.	Poor	30 to 50	0	0 to 0·5	*Land for Barley.* The soils which are rich in humus, and contain lime, are well-suited even for wheat and spelt, and often approach nearly to the foregoing kinds. They are, moreover, suited for Triticum dicoccum? (Emmer), one-grained wheat (Einkorn), rye, oats, rape (Reps), flax, and clover.
		Interm.	30 to 50	0	0·5 to 1·5	
		Rich	30 to 50	0	1·5 to 5·0	
	With Lime.	Poor	30 to 50	0·5 to 5·0	0 to 0·5

		Rich	20 to 30	0·5 to 5·0	1·5 to 5·0	
4. Loamy Sands. — Not more than 20 nor less than 10 per cent. of Clay. Less than 5 per cent. of Lime.	Without Lime.	Poor	10 to 20	0	0 to 0·5	*Land for Oats and Rye.* Barley thrives well in those rich in humus. They are also well suited for buckwheat. Wheat, spelt, and clover do not succeed.
		Interm.	10 to 20	0	0·5 to 1·5	
		Rich	10 to 20	0	1·5 to 5·0	
	With Lime.	Poor	10 to 20	0·5 to 5·0	0 to 0·5	
		Interm.	10 to 20	0·5 to 5·0	0·5 to 1·5	
		Rich	10 to 20	0·5 to 5·0	1·5 to 5·0	
5. Sandy Soils. — Not more than 10 per cent. of Clay. Less than 5 per cent. of Lime.	Without Lime.	Poor	0 to 10	0	0 to 0·5	*Land for Rye.* Of less value; often cultivated only every third year, and the poor land often not at all. Those containing humus are chiefly fit for buckwheat, oats, hemp, tobacco, potatoes, and spergula arvensis.
		Interm.	0 to 10	0	0·5 to 1·5	
		Rich	0 to 10	0	1·5 to 5·0	
	With Lime.	Poor	0 to 10	0·5 to 5·0	0 to 0·5	
		Interm.	0 to 10	0·5 to 5·0	0·5 to 1·5	
		Rich	0 to 10	0·5 to 5·0	1·5 to 5·0	
6. Marly Soils. — More than 5, not more than 20 per cent. of Lime.	Argillaceous.	Poor	Above 50	2 to 20	0 to 0·5	Chiefly suited for wheat and spelt, together with lucern and sainfoin.
		Interm.	„ 50	5 to 20	0·5 to 1·5	
		Rich	„ 50	5 to 20	1·5 to 5·0	
	Loamy.	Poor	30 to 50	5 to 20	0 to 0·5	Less suited for wheat and spelt, more so for barley, Triticum dicoccum, and T. monococcum, but are amongst the most fertile soils.
		Interm.	30 to 50	5 to 20	0·5 to 1·5	
		Rich	30 to 50	5 to 20	1·5 to 5·0	
	Belonging to the Sandy Loams.	Poor	20 to 30	5 to 20	0 to 0·5	Barley and oats.
		Interm.	20 to 30	5 to 20	0·5 to 1·5	
		Rich	20 to 30	5 to 20	1·5 to 5·0	
	Belonging to the Loamy Sands.	Poor	10 to 20	5 to 20	0 to 0·5	Oats and rye.
		Interm.	10 to 20	5 to 20	0·5 to 1·5	
		Rich	10 to 20	5 to 20	1·5 to 5·0	
	Humous.	Clayey	Above 50	5 to 20	Above 5·0	The humous, and argillaceous marly soils are amongst the best which exist
		Loamy	30 to 50	5 to 20	„ 5·0	
		Sandy	20 to 30	5 to 20	„ 5·0	
7. Calcareous Soils. — Containing more than 20 per cent. of Lime.	Argillaceous.	Poor	Above 50	Above 20	0 to 0·5	The argillaceous soils often approach in value to the argillaceous marls; the remaining orders of both these classes equally correspond one with the other; to the most valuable belongs, as in the former case, the humous. Those wanting in humus require much manure. Those rich in clay are well suited for spelt and wheat; oats, Triticum dicoccum, lucern, and sainfoin thrive in them. Their value is much decreased by containing an excess of lime.
		Interm.	„ 50	„ 20	0·5 to 1·5

			Without Lime.		„ 5·0	

* This, of course, chiefly applies to the soil and climate of Germany. † Remainder,—any portion of sand, less than 80 per cent.

The Characters of Soils. — The compositional characters of soils have already been sufficiently adverted to in the section on the "Composition of Soils;" and their adaptational characters, for the various kinds of ordinary cropping, are instructively glanced at in the last column of the tabular classification of soils which we have given from Schübler. But their economical characters, or those which concern the facilities and rewards and accidents of tillage,—their indicational characters, or those which reveal important intrinsic properties through the medium of colour,—their relative chemical characters, or those which concern the kind and degrees of connexion with the chemical agencies of the atmosphere,—their relative geological characters, or those which concern the kind and degree of connexion with the agencies and influences of the subsoil, — and their intrinsic mutational characters, or those which concern the changes or fluctuations of constitution resulting from successions of vegetable growth,—all these also claim to be well understood; and we shall here devote a paragraph to each class.

The economical characters of soils comprise a subclass which might be called the mechanical, and they also impinge upon, or partially comprise, some of the compositional, the chemical, and the geological; yet they constitute a sufficiently distinct class, and eminently deserve to be treated as one on account of their mutual connexions and their aggregate importance. A stiff or heavy soil is one difficult to be worked, such as most clays; and a free or light soil is one easy to be worked, such as all sands and gravels, most loamy sands, and some sandy chalks and limestone gravels. A hard soil is one which constantly tends to dry cohesion and dry cloddiness, however well or often worked; and a soft soil is one which constantly tends to crumbliness and incohesion, in consequence of being too silicious, or too often ploughed, or too much marled. A wet soil is one which is continually so, or which cannot easily or long be put into the opposite condition, such as a clay upon a retentive subsoil; and a dry soil is the opposite of a wet one, such as sand or loamy sand upon an open subsoil. A retentive or close soil is one which does not allow the ready permeation of surface water, but holds much of it till it be dissipated by evaporation; and an irretentive or open soil, is one which readily allows the infiltration of water, and holds no collections or stagnations of it either on the surface or in the interior. A smooth soil is even and slippery when wet; a rough soil is irregular and corrugated when dry; a coarse soil consists, in a considerable degree, of large granules and unreduced boulders and fragments; a fine soil is either minutely granular or, in a considerable degree, impalpably powdery; and a fine-skinned soil assumes either a smooth or a finely granulated surface when finished off by tillage. A deep soil comprises a great depth of mould or of alluvium, or has a somewhat uniform composition from the surface down to a greater depth than the plough can reach; and a thin or shallow one comprises a comparatively thin stratum of mould, and passes soon into the botanical subsoil, but, in many instances, is capable of being easily deepened by courses of tillage, trenching, cultivation, and manuring. A rich soil yields a large return of produce for a moderate quantity of manure; and a poor one yields only a middling or even small return of produce for an enormous quantity of manure. A grateful soil yields larger returns of produce than might be fairly expected from the labour and manure bestowed upon it; a kindly soil makes a regular and steady and corresponding return for every ameliorating operation performed upon it; a churlish one yields smaller returns of produce than might be fairly expected from the labour and manure bestowed upon it; and a hungry one yields ordinary returns of produce, or is maintained in a moderately fertile condition, only when it is dosed with large and frequent supplies of manure. A sharp soil is either a warm, dry, and early one, bringing crops to a speedier maturity than other soils in the same circumstances of subsoil, situation, climate, and georgy,—or it is a peculiarly open one, which contains so large a proportion of small gritty stones as quickly to clear up the plough-irons; and a deaf soil is the opposite of a sharp one in the latter sense, containing so large a proportion of soft, spongy, inert vegetable matter as to act chokingly against the plough or be carried forward on its bosom.

The colours of soils, regarded as indicational characters, reveal in some instances the constitution of soils, in others their economical properties, in others their chemical capacities, and in others the changes which they undergo from cultivation. A black humous soil consists mainly of crude peat or of deep vegetable mould, and is rapidly absorbent of heat, and has been observed to rise, in one hour, by simple exposure to sunshine, from a temperature of 65° to a temperature of 88°. A white calcareous soil contains a large proportion of chalk, and is very slowly absorbent of heat, and has been observed to acquire only 4° of additional temperature in the same circumstances in which a black humous soil acquired 33°. Brown and red soils acquire comparatively high degrees of temperature, and, in common with the black, are called warm soils; and yellow, pale, bluish, and grey soils acquire comparatively low degrees of temperature, and, in common with the calcareous white, are called cold soils. Brown and red soils vary in gradations of hue from hair-auburn to dark chestnut, and include the rich and numerous sub-class popularly called hazel soils, and owe their characteristic tints to various combinations of oxide of iron, and comprise a large proportion of the loamy soils, the sandy loams, and the loamy sands. Yellow, pale, grey, and bluish soils com-

prise most of the argillaceous soils, and a few of the stiffest loams. Black soils are often churlish and generally deaf; brown soils are often kindly and generally sharp and grateful; and red soils are always rich. The yellowish grey, the dull red, and the dull brown are very little or not at all altered in tint by cultivation; but the bluish, the yellow, and the bright red become darker and duller by ploughing and manuring.

The relative chemical characters of soils, both with reference to atmospherical connexions and with reference to intrinsic action, are very powerfully and variously modified by the circumstances of drainage. See the article DRAINING.—The circulation of air through soils, together with free play to the important action of oxygen, is mightily controlled by natural porosity, and by all those operations of georgy and culture, by which porosity is artificially increased or maintained. See the article AERATION.—The absorption of carbonic acid, ammonia, phosphuretted hydrogen, sulphuretted hydrogen, and other importantly nutritional gases which either float in the atmosphere or ascend toward it from the decomposition of organic remains and of putrescent manures, is effected far more by some soils than by others,—and most of all by such as possess a maximum of carbonaceous matter in a state akin to that of charcoal. See the article ABSORPTION IN CHEMISTRY.—The various absorption of heat by different soils has already been adverted to in connexion with the colour-characters; and may here be further noticed in the words of Sir Humphrey Davy, "Some soils are much more heated by the rays of the sun, all other circumstances being equal, than others, and soils brought to the same degree of heat cool in different times, that is, some cool much faster than others. This property has been very little attended to in a philosophical point of view; yet it is of the highest importance in agriculture. In general, soils that consist principally of a stiff white clay are difficultly heated; and being usually very moist, they retain their heat only for a short time. Chalks are similar in one respect, that they are difficultly heated; but being drier they retain their heat longer, less being consumed in causing the evaporation of their moisture. A black soil, containing much soft vegetable matter, is most heated by the sun and air; and the coloured soils, and the soils containing much carbonaceous matter, or ferruginous matter, exposed under equal circumstances to the sun, acquire a much higher temperature than pale-coloured soils. When soils are perfectly dry, those that most readily become heated by the solar rays likewise cool most rapidly; but I have ascertained by experiment, that the darkest coloured dry soil, (that which contains abundance of animal or vegetable matter, substances which most facilitate the diminution of temperature,) when heated to the same degree, provided it be within the common limits of the effect of solar heat, will cool more slowly than a wet pale soil, entirely composed of earthy matter."—The retention of the decomposing substance or of the recombined principles of organic remains, especially as artificially supplied in the form of manure, is much greater and more economizing by argillaceous and loamy and calcareous soils than by silicious ones, or by sandy soils containing a considerable intermixture of lime or chalk than by mere sands and gravels.—Close soils and open ones are very differently affected by frost and thaw. All clays and stiff loams, in consequence of the great expansion which results from the freezing of the water in their interstices, are more dissevered and disintegrated by frost than by the most elaborate tillage; and when thaw comes, they are left open and porous, freely exposed to the circulation of air and moisture, which decomposes their alkaline constituents, elaborates their stores of inorganic nutriment for plants, and renders their whole mass almost as powdery and "mellow" as that of naturally open soils. But sands, loamy sands, many calcareous and humous soils, and even some sandy loams, when frozen soon after rain, or otherwise in a wet state, are so greatly expanded as to be icy and resonant; and, when thawed, they retain their increased bulk, and have a largely cellular or honeycombed texture, and suffer erosion and winnowing by the excessive permeation of air, and allow their young plants, particularly wheat and red clover, to be loosened from their root-hold, "thrown out," and either ruptured or starved to death.—The absorbing of moisture from the air in dry conditions of the ground, so as by its imbibitions during the night to counteract the effect of evaporation during the day, is a function eminently connected with fertility, and is performed in widely different degrees by different soils. Very powdery or finely pulverized soils of any one kind absorb much more moisture than coarsely granular or badly tilled ones of the same kind; and humous substances in any soil absorb more moisture than fine carbonate of magnesia,—fine carbonate of magnesia more than garden mould or grey pure clay,—garden mould or grey pure clay more than loamy clay or slaty marl or sandy clay,—and any of these three very greatly more than gypsum powder, calcareous sand, or silicious sand. The stiff clays approaching in nature to pipe clays, which imbibe the greatest quantity of water when it is poured upon them in a liquid form, do not by any means absorb the greatest quantity of moisture from the atmosphere in dry weather, but consolidate and contract and present a diminished and close surface to the air, and become arid and exsiccated, and eventually allow their vegetation to be almost as severely burnt up as on sands. Soils, on the other hand, which are not remarkable for imbibing large doses of water in its liquid state, but which have an open texture and a finely divided condition,

and which contain a fair proportion of loamy clay and vegetable matter, absorb large supplies of moisture from the atmosphere in dry weather, and at the same time do not become cohesive or pultaceous after rains. The following table from Schübler shows the quantity of moisture absorbed from the atmosphere, in respectively 12, 24, 48, and 72 hours, by 1,000 grains of each of 13 substances, spread on a surface of 50 square inches:—

Substances.	In 12 hours.	In 24 hours.	In 48 hours.	In 72 hours.
Silicious sand	0	0	0	0
Calcareous sand	2	3	3	3
Gypsum powder	1	1	1	1
Sandy clay	21	26	28	28
Loamy clay	25	30	34	35
Stiff clay	30	36	40	41
Grey pure clay	37	42	48	49
Fine carbonate of lime	26	31	35	35
Fine carbonate of magnesia	69	76	80	82
Humus	80	97	110	120
Garden mould	35	45	50	52
Arable soil	16	22	23	23
Slaty marl	24	29	32	33

The relative geological characters of soils, or those which involve their connexion with the agencies and influences of the subsoil, have reference partly to their original constitution, partly to the local facilities for improving them, and partly or even chiefly to the circulation of moisture through them or to the circumstances of their drainage.—Soils which rest directly upon solid rock, whether on hill or plain, generally owe their mineral constituents to the disintegrations immediately below and around them; so that their general nature and value, in so far as these depend upon their mere original composition, may be accurately estimated by reference to the geognostic formations on which they lie. Soils formed directly on granite, quartz, serpentine, and generally on silicious primitive rocks are barren; those formed directly on magnesian limestone are bad; those formed directly on all tolerably pure calcareous limestones are productive; those formed directly on the shales and sandstones intermediate between the transition and the tertiary rocks, are bad, indifferent, or good, according to the predominance of silica in the rocks or to the degrees of its intermixture with alumina and lime; and those formed directly on the basalts, greenstones, and porphyries of the trap rocks are generally fertile. See also some statements in the article Barren Soils. —Soils which rest upon earthy strata may, when properly worked by intelligent and skilful husbandry, owe more of their practical worth or worthlessness to the depth and the nature of these strata than to their own composition When the under-strata are deep and porous, no expense requires to be incurred for forming and maintaining a system of artificial subsoil drainage; when they are comparatively rich in organic matter and in alkalies and salts, they afford a ready mine for the deepening or renovating or enriching of the soil by the simple process of trenching or trench-ploughing; and when they contain a supply of any necessary ingredient in which the soil is deficient, or which would tend to improve it, as of clay beneath sand or of limestone gravel beneath peat, they offer the amplest facility for effecting improvement by textural intermixture. But, on the other hand, when the under-strata are stubbornly retentive, a system of artificial subsoil drainage is essential to fertility; when they are poor in organic matter and in salts, and especially when they contain noxious metallic oxides, they would injure the soil, and not improve it, by being trenched up; when they are minerally the same in nature as the soil, they offer little or nothing for textural improvement; and when they are porous and lie very near the surface, they both starve all deep-rooting plants, and occasion a rapid exhaustion of internal moisture at a time of drought.—The strata immediately beneath the soil, whether they be solid or earthy, differ widely in their effects upon the circulation of air and moisture, or upon all those properties of soil which are dependent on drainage.

The mutational characters of soils might be so comprehensively defined as to comprise all sorts of changes whatever which take place in soils both naturally from the agencies of meteorology, chemistry, and vegetation, and artificially from the operations of georgy, tillage, manuring, and cropping; but they are understood here in so restricted a sense as to comprise only the changes and fluctuations which result from successions of vegetable growth, partly in a natural way, but chiefly in courses of cropping; and even as thus limited in meaning, they present to the farmer a great and diversified and eminently important subject of study,—no less, in fact, than the whole question of constant mutations in composition and fertility arising, on the one hand, from the withdrawal of ingredients by unreturned weeds, crops, and cattle, and, on the other, from the adding of ingredients through the medium of fallowing and of feeding-off and in the form of manure. The subject, however, belongs rather to the chapter of current cultivation than to the chapter of soils, and has already been pretty fully discussed, though in an incidental way, in the articles Manure and Rotation of Crops; and it is introduced here principally for the sake of reminding intelligent farmers that, in the present advanced state of agricultural science, they may enjoy the luxury and reap the benefit of keeping an estimate-account of the fluctuating powers of every field, so as to show at a glance the balance between fertility withdrawn by crops and stock and fertility imparted by ameliorations and manurings,—and of presenting to them the following table, by the help of which, along with that of the analyses of the several manures given in their proper places, they may see the principles on which such an account must be framed:

100,000 lbs, or about 50 tons of	Contain of Volatizable Ingredients—in lb.		Fixed Ingredients—in lb.											
	Water and Carbon.	Azote.	Potash.	Soda.	Lime.	Magnesia.	Alumina.	Oxide of Iron.	Oxide of Manganese.	Silica.	Sulphuric Acid.	Phosphoric Acid.	Chlorine.	Total of fixed Ingredients.

* So in Sprengel, but we probably ought to read 69·0.

† In Sprengel 40·0, but this is a manifest misprint.

The Offices of Soils.—Soil affords mechanical support to plants growing in it. Plants can neither stand of themselves on the surface of the ground, nor move from place to place in quest of their daily food, but require to remain long on one spot, and there to send their roots downward, and to spread their radicles beneath the surface. And the soil is exactly adapted to their wants. Being a finely divided solid, it permits their roots and radicles to push through it in all directions; and being, at the same time, closely aggregated, it holds them sufficiently fast to prevent them from falling by their own gravity, and from being torn up or overwhelmed by ordinary winds; and being also permeated by air and moisture, it maintains them in the precise position and circumstances which are suitable to their constant feeding. The different kinds of soil, too, have exactly the varieties of texture which are best adapted to the form and habits and wants of the particular species of plants which naturally inhabit them.

Soil supplies part of the inorganic food of plants, and serves as a ready vehicle for the reception of other parts. Its stores of silica, alumina, and lime afford supplies of the nutrimental principles derivable from them, which are in many instances inexhaustible,—and in most of at least long continuance; and its mechanical condition and capacities receive in the readiest manner all sorts of natural and artificial additions of other nutrimental substances, and store them up in ways which both make them most facilely accessible to the roots of plants, and most effectually prevent their waste or dissipation by interfering causes.

Soil acts as the stomach of plants, or as the laboratory in which their food is prepared for absorption by their spongioles. The substances which yield this food, whether as they exist naturally in virgin soils or as they are artificially added to soils which have been long in cultivation, require in some instances to be dissolved, and in most to be also decomposed and recombined before they assume the form of food; and at the same time, either the substances themselves or the principles which result from them must be so diffused, economized, and progressively reduced as to afford a continuous contribution of nourishment around all the parts and periphery of each plant's roots, throughout the whole period of its existence. The powers by which the soil achieves so great and complicated results are mainly its own mechanism, the chemistry of its own ingredients, and the agencies of moisture, air, heat, light, and electricity; and the methods and intricacies in which these work and co-operate, so far as they have been yet investigated, are a most imposing instance of the beauty and complexity, the wisdom and magnificence of the physical ordinances of the all-beneficent Creator. A simple glimpse at them—sufficient for farming purposes, and also for setting the mind a-thinking—is afforded by the following extract from a paper by Dr. Madden:—"The mineral or permanent constituents of soil are capable of being divided into two distinct classes, independently of their chemical nature, viz., into coarse and fine, or into visible particles and impalpable powder. The impalpable matter of soil contains all its most important ingredients; for the remainder, or coarse particles, contains, in addition to pure mineral matter, merely the crude undecomposed vegetable fibre, &c., which is utterly useless to plants until, by putrefaction or otherwise, it becomes disintegrated and intimately combined with the impalpable matter. The use of the coarser parts is therefore merely to render the soil more permeable to moisture, air, heat, &c., and in this manner to assist mechanically in the preparation of the food of plants. When manure is added to soil, the following series of changes takes place:—1. The soluble matters are washed away from the straw and other undecomposed substances, by the first rain that falls, and, sinking into the earth, are immediately absorbed (supposing no plants are growing in the neighbourhood) by the impalpable matters of the soil. 2. If the soil should not have been previously rich, a certain quantity of the soluble manure will enter into chemical combination with the sand, clay, and chalk, of which the impalpable matter is composed, and thus be rendered insoluble, and consequently for the present useless. 3. But should the finely divided parts of the soil be already saturated with organic matter,—which, however, as above stated, will have been rendered insoluble by chemical combination,—the newly added soluble matter is, nevertheless, absorbed by the mass, although now it acts in a totally different manner. 4. The soluble organic matter of manure, when brought into contact with insoluble organic matter, of whatever origin, acts as a ferment upon it, and causes it to undergo various changes, by which the chemical attraction between it and the clay, sand, chalk, &c., are overcome, and consequently it again becomes free in a soluble state, or, in other words, in a fit state for absorption by plants. 5. But when, by the operations of tillage, any part of the chemically combined organic matter is brought sufficiently near the surface to come freely in contact with air, a different series of changes takes place; oxygen is absorbed, and the organic matter is in this manner changed in its nature, and rendered much less easily decomposed, and, in fact, although no longer combined with the clay, chalk, &c., requires the addition of fermenting matters, or some alkaline salt, in order that it may be again rendered capable of solution. 6. At this point, the saline impregnations of soil come into play, and none more so than common salt or muriate of soda. This exists in almost every manure, so that it very generally is to be found in all cultivated soil. When this salt is brought into con-

tact with carbonate of lime (chalk), a gradual change takes place, and the resulting compounds are muriate of lime and carbonate of soda; which latter is a powerful alkali, and is of great value, on account of its capability of acting upon oxidized organic matter. 7. Thus the organic matter has again become combined with saline matter, but this time it forms a very soluble salt, which consequently is absorbed by plants, and is more useful than it would have been previously, because it is more highly oxidized. 8. As, however, the plants do not require so large a quantity of alkaline matter as they would in this way receive, the superabundant portion is returned to the soil, with other excrementitious matters, and thus, by coming into contact with the muriate of lime, produced in the manner formerly related, a contrary change takes place, and carbonate of lime and muriate of soda are reproduced. For, strange as it may appear to those not conversant with chemistry, although carbonate of lime and muriate of soda, when in contact in a moist state, are gradually converted into muriate of lime and carbonate of soda, still, if these latter salts meet together in solution, they immediately resume their former state of chalk and common salt. These are a few of the very complicated changes which are constantly occurring in soil; but a careful consideration of them will enable us to draw the following important practical deduction, viz., that multitudinous as they appear, still soil is so admirably adapted for the duties which it has to perform, that the farmer has merely from time to time to add fermenting matters to his soil, and he may rest assured of his plants never lacking their proper nourishment."

The Peculiar Vegetations of Soils.—Many plants prosper equally on many kinds of soils and in widely different situations; most are diffused over a great diversity of surface by means of some one or more of the mighty agencies which are everywhere at work for covering all the earth with vegetable wealth and beauty; and few are so entirely dependent on the composition and depth and texture of soils, irrespective of capacity for the free play of heat and moisture and atmospheric influences, as to afford invariable indication of the mineral and economical and chemical characters of the ground on which they grow. Yet some great groups and families of them always affect peculiar conditions of land or water or elevation, and therefore make striking intimation of the presence of these conditions wherever they exist. "Thus," to adopt the words of Professor Macgillivray, "if, while traversing an extended heath, we observe at a distance a spot covered with fresh verdure, we infer that the soil there is certainly not peat; and if, on approaching it, we see poæ, viciæ, and other plants usually found in rich pasture, we infer that the soil is vegetable; and so of other soils. If, on the other hand, in a rich country, we see tracts, whether of hill or plain, covered with a brown vegetation, which we know to be heath, we infer that the soil is peat. Still, even among these general appearances, there are few that have direct reference to soil. Thus, on seeing a long line of trees, which we know by their physiognomy to be alders or willows, we infer that a river flows beside them, but we can make no inference with respect to the soil. And thus, were it possible that we should be led blindfolded to a spot, in which we should open our eyes upon a rivulet, margined with bright green moss, among which *Saxifraga stellaris, Alchemilla alpina, Silene acaulis,* appeared here and there, we might assuredly pronounce ourselves in an alpine region; but what the peculiar soil of the spot might be, we would require to remove the turf to discover, and thus trust to the colour, texture, adhesion, and other qualities of the soil itself for a disclosure of its nature, rather than to anything growing upon its surface. Thus we see that Nature, simple in her grand plans, yet complex even to infinity in her details of execution, presents nothing of which we can acquire a tolerable knowledge, by viewing it on one side only, or which the mind can grasp by employing a single principal or pervading idea for that purpose. The grand principle of vegetation is simple in its design; but view it in detail, and its complication astonishes and bewilders. To become the abode of animals, it was necessary that the earth should be covered with vegetables; but from the cedar of Lebanon to the small plant (whatever that may be) that grows on the wall, from the magnificent jagua of tropical America to the diminutive radiola of northern Europe, not to take other examples still more striking, how multiplied the proportions, the forms, the colours, the qualities of all kinds, and how different the circumstances! It is the same sun that calls forth, and, when thus elicited, gives vigour to the vegetation, the same earth that supports it, the same moisture that swells its vessels, the same air that furnishes the medium in which it lives; but amid all this singleness of general, how multiple the variations of partial or constituent causes, and how infinitely diversified their results!"

The comparatively few British plants, however, which have a certain and uniform character of habitat, perform a valuable service to intelligent observers, in some cases by indicating the presence or predominance of certain constituents in the soil, in others by indicating the aggregate composition of the soil, in others by indicating the comparative states of different specimens of soil of the same generic composition, in others by indicating the pressure or excessive power of some deteriorating influence which is capable of correction, and in many by suggesting or revealing errors which have been committed in the management of land or methods which may be adopted for reclamation or enrichment. We

shall here give two sets of indications, the one in an extract from a paper by Professor Macgillivray, and the other in a digest of a paper by Mr. Gorrie,—the former showing in a general way the peculiar vegetations of different kinds and conditions of British soils, and the latter showing the characteristic wild vegetation of each principal kind of soil in respectively its natural and its cultivated states.

"Loose sand requires no indications by vegetables, its nature being rendered too obvious by other circumstances. Luxuriant tufts of Arundo arenaria, either by itself, or mixed with Triticum junceum, Galium verum, and some other vegetables, frequently occur in this soil. Calcareous sand and silicious sand are not distinguished apart by any peculiar plants. They may, however, be readily distinguished by simple inspection. Intermixture of pasture plants, and especially Galium verum, Achillæa millefolium, and grasses, with Arundo arenaria, indicate that the sand is more or less fixed, and that it is tolerably well secured against drifting. The existence of peat is invariably indicated by Calluna vulgaris, Erica cinerea, E. tetralix. It is to be suspected also wherever Myrica gale, Droseræ, Eriophora, numerous Carices, and Melica cœrulea appear. Soft, friable, scaly or laminar peat, is indicated by a vegetation consisting chiefly of Calluna vulgaris, Erica cinerea, Melica cœrulea, intermixed with Carices, Junci, Scirpi, Mosses, and Lichens. Fibrous, tenacious, spongy peat, is indicated by a vegetation consisting chiefly of Cyperaceæ, Carices, Scirpi, and Junci, especially Juncus cæspitosus and Eriophorum vaginatum, with comparatively little heath. Compact, brittle, hard peat, is indicated chiefly on declivities and in elevated situations by a vegetation consisting in a great part of Gramineæ, such as Melica cœrulea, Aira flexuosa, together with Cyperaceæ and heath. The softish friable peat in which remains of ligneous vegetables occur, is not indicated by any peculiarity of vegetation differing from that indicative of the first kind of peat mentioned. It is almost always to be found in low and level places, and is frequently swampy at the surface, with great tufts or islets, covered with heath. Calluna vulgaris or Erica cinerea, when luxuriant and close, indicate a gravelly soil at no great depth. Pinus sylvestris growing in peat indicates that it is thin, and that the subsoil is sandy or gravelly. Scirpi, Carices, and Eriophora, thriving in peat, indicate an abundant supply of moisture, owing either to a subsoil of clay or solid rock. On the contrary, a vegetation stunted, and liable to be burnt up in dry weather, indicates, in general, dryness arising from a subsoil of sand. The cessation of Erica and Calluna upon mountains indicates either the cessation of peat soil, or approximation to the line of snow. On open heaths, Trientalis europæa and Anemone nemorosa indicate great dryness, and manifest a disposition favourable to the growth of Pinus sylvestris, if planted on them. Heath overgrown or much intermixed with lichens, indicates too great an elevation for the successful cultivation of corn. The same indication is made by the existence of alpine plants, such as Saxifraga stellaris, Veronica alpina, Thalictrum alpinum, &c. Great profusion and luxuriance of Scirpus cæspitosus in low heaths, indicate that, although excellent for summer pasturage, they are unfit for wintering, from their great wetness. The existence of any other tree than Pinus sylvestris in peat soil, shows that the subsoil comes very near the surface. With respect to cultivation of peat soil, some indications are also furnished by the plants growing in it. Peat, of which the surface is even, and continuously covered with Calluna or Erica, is in general capable of being taken in, because the gravel comes so near the surface that it may be reached by the plough. On the other hand, low tracts of peat, with great tufts of heath, separated by bogs, are incapable of being reclaimed, without previous draining, and, after all, the peat is too deep to form a tolerable soil. Spongy, fibrous peat is the most intractable of all the varieties, because, from its tenacity, it cannot be made to mingle with gravel or sand. The great mass of vegetation, or, as it may be called, the standard vegetation of the country, being diffused over every sort of soil, sandy, gravelly, gritty, clayey or vegetable, no particular indications are afforded by it of the nature of the soil, unless with respect to its luxuriance, which yet depends upon other circumstances, more than upon the quality of the soil. Trifolia, Viciæ, Lathyrus pratensis, mixed with grasses, forming the principal part of the vegetation, and growing luxuriantly, indicate a good vegetable soil, well supplied with moisture. Abundance of Thymus serpyllum indicates not so much any particular soil, as dryness of soil, or great thinness. Senecio Jacobæa, in general, indicates a good depth of good soil. Linum catharticum, Thymus serpyllum, Apargia autumnalis, Hieracium pilosella, indicate dry, if not gravelly or sandy soil, in pasture grounds. Iris pseudacorus, Juncus acutiflorus, Cardamine pratensis, and Lychnis flos-cuculi, in such, indicate a good soil, with a plentiful, or more frequently an overabundant, supply of moisture. In pasture-grounds, in general, the existence of Poa trivialis, Triticum repens, Potentilla anserina, Plantago lanceolata, P. media, Senecio Jacobæa, indicate a soil of good quality, capable of being cultivated with advantage. A stunted and, in hot weather, burnt-up herbage, indicates the approximation of the rock to the surface, or extreme dryness of soil. Sandy pasture-grounds are always characterized by a peculiar fineness of vegetation, producing a comparatively large portion of the most nutritious species, excepting when furze or broom has got into them, in which case these plants frequently banish or choke up the more useful kinds. An intermixture, however small, of Erica or Calluna with pasture plants, indicates that the soil is more or less peaty; Orchideæ, and especially Orchis maculata, abundant in pasture-grounds, affords the same indication. Pteris aquilina, in such grounds, especially when the other vegetation consists chiefly of grasses, affords a very favourable idea of the soil, which has commonly a large proportion of vegetable earth in it, where this plant grows luxuriantly. Gravelly or gritty soil is indicated by the poverty of the vegetation. Aira caryophyllæa, A. præcox, Rumex acetosella, are among the ordinary inmates of such soil. When intermixed with clay, the vegetation is scanty, and consists chiefly of grasses. Clayey soil is indicated by the depressed and straggling nature of the vegetation, which consists chiefly of grasses of the genera Poa, Agrostis, and Festuca. By streams, a great profusion of Tussilago farfara generally indicates a clayey soil, and of T. petasites a deep rich vegetable soil. In the natural uncultivated state, vegetable soil is indicated, near the habitation of man, by Urtica dioica, Rumex obtusifolius, Artemisia vulgaris, Poa annua, P. pratensis, and Tanacetum vulgare, although nevertheless all these species may be found so situated in many varieties of soil; in pastures, by Trifolium repens, T. pratense, Poa annua, Plantago media, P. lanceolata, Vicia Cracca, Bellis perennis."

Rich alluvial soils recently deposited by the sides of low winding rivers are characterized, in their uncultivated state, by the growth of common reed, *Arundo phragmites*, round-headed rush, *Juncus conglomeratus*, white bent, *Agrostis alba*, reed meadow-grass, *Poa aquatica*, and floating meadow-grass, *Poa*

fluitans. When these soils have been drained and brought into cultivation, they are not infested by any of these five plants as weeds except *Arundo phragmites;* and they generally produce such luxuriant crops of corn as to be remarkably free from all sorts of weeds; but when they are indifferently farmed, they become distinguished by the presence of the corn thistle, *Cnicus arvensis.*—The clay soils which constitute the greater proportion of low carse lands are older and have been longer in a dry state than rich recent alluviums; and the plants which appear on them, in their natural state, are more numerous, and indicate the firmer texture of the ground. These are sweet briar, *Rosa rubiginosa,* common alder, *Alnus glutinosa,* common sallow, *Salix caprea,* common furze, *Ulex europæus,* meadow sweet, *Spirea ulmaria,* wild angelica, *Angelica sylvestris,* great spearwort, *Ranunculus lingua,* and common sorrel, *Rumex acetosa.* When such clay soils are subjected to cultivation, the shrubs and herbaceous plants are easily rooted out; and the weeds that appear are introduced either amongst the seed-grain or amongst the dung. These are, broad-leaved dock, *Rumex obtusifolius,* groundsel, *Senecio vulgaris,* nipplewort, *Lapsana communis,* cockle, *Agrostemma githago,* wild chamomile, *Matricaria chamomilla,* and common sow thistle, *Sonchus oleraceus.* The agrostemma and wild chamomile are introduced amongst the wheat and grass seeds, and maintain their ground among the subsequent crops.—The poorer clay soils, including the red or rock marl-clay, often found incumbent on red sandstone rocks, and those yellow ochry clays that are often met with in elevated situations, produce, in their natural state, the following perennial-rooted herbaceous plants,—knobby rooted figwort, *Scrophularia nodosa,* upright meadow crowfoot, *Ranunculus acris,* tufted hair-grass, *Aira cæspitosa,* corn horse-tail, *Equisetum arvense,* and marsh woundwort, *Stachys palustris.* When these soils are brought under tillage, the common colt's-foot, *Tussilago farfara,* grows amongst the corn crops, and is eradicated with difficulty when there is any calcareous sand mixed with the clay. The annual weeds, indicative of such clay soils, are, wild mustard, *Sinapis arvensis,* red eye-bright, *Bartsia odontites,* peach-wort, *Polygonum persicaria,* and knotgrass, *Polygonum aviculare.*—The natural productions peculiar to strong black loam, incumbent on whinstone or limestone rock, and reposing on a brownish open bottom above that rock, are bladder campion, *Silene inflata,* toad-flax, *Antirrhinum linaria,* field scabious, *Scabiosa arvensis,* great knapweed, *Centaurea scabiosa,* red shanks, *Polygonum amphibium,* and rough cock's-foot grass, *Dactylis glomerata.* When the rock is near the surface, the plants are, common rest harrow, *Ononis arvensis,* hare's-foot trefoil, *Trifolium arvense,* and hop trefoil, *Trifolium procumbens.* When soil of this nature is brought under tillage, the plants above enumerated gradually disappear. Under indifferent management, however, the *Polygonum amphibium* and *Ononis arvensis* are not readily extirpated. The plants found amongst the corns are, or ought to be, chiefly annuals, of which the following are the most characteristic,—scarlet pimpernel, *Anagallis arvensis,* ivy-leaved speedwell, *Veronica hederifolia,* needle chervil, *Scandix pecten-veneris,* black mustard, *Sinapis nigra,* and hairy tare or fetter, *Ervum hirsutum.* The four kinds of soil now enumerated, if they are met with within the 56° of north latitude, and under an elevation of 400 feet above the level of the sea, are capable of carrying wheat in perfection. The clays, if under an elevation of 300 feet, will produce excellent crops of beans with good management. Oats and barley may also form part of the rotation; but potatoes and turnips, except on the first and fourth kinds, are raised with difficulty. The fourth soil is seldom found at a high elevation, and is what farmers term 'land that carries a clod,' highly favourable for the culture of all sorts of corn and green crops.—Nearly allied to this is light black loam, on a clay subsoil, only it has a greater proportion of sand amongst the loam or vegetable matter, and less of clay or binding matter in its composition. The subsoil is also more various. Sometimes light black loam is found reposing on a clay or impervious 'till' bottom, spongy in the winter months, and apt to throw out plants by spring frosts. Many of the plants are found in soil of this nature that are to be met with on the poorer clays. The most predominant, when the soil is in a natural state, are, soft or common rush, *Juncus effusus,* sneezewort, *Achillea ptarmica,* wild tansy or silver-weed, *Potentilla anserina,* and mugwort, *Artemisia vulgaris.* The last continues some time after the ground is cultivated. The annual plants, indicative of this soil and subsoil, are, charlock, *Raphanus raphanistrum,* sheep's sorrel, *Rumex acetosella,* and corn marygold, *Chrysanthemum segetum.* In wet sandy furrows, and at the ends of ridges, toad-rush, *Juncus bufonius,* sometimes occurs. None of the above plants indicate great richness in the soil. Oats, barley, pease, potatoes, and turnips, succeed well on such soils, under favourable cultivation; and when there is a quantity of small stones on the surface, flax will be raised with advantage.—When light black loam is found on an open or gravelly subsoil, the plants most conspicuous are, common broom, *Genista scoparia,* common furze, *Ulex europæus,* black knap-weed, *Centaurea nigra,* yellow bed-straw, *Galium verum,* and common ragwort, *Senecio jacobea.* When, by cultivation, these plants are displaced they are followed by common corn mint, *Mentha arvensis,* blue bottle, *Centaurea cyanus,* corn madder, *Sherardia arvensis,* corn gromwell, *Lithospermum arvense,* parsley piert, *Alchemilla arvensis,* and tall knot-grass, *Avena elatior,*—which last is a troublesome perennial plant in light lands. The common corn thistle will also be found a troublesome intruder where the furze was formerly established. Where the above plants are found to predominate, corn crops of every description will succeed, if the climate is favourable. The soil may be found rather light for beans, and too open for wheat; but eating off turnips with sheep, and allowing the grass division to be two years under pasture, will improve the texture.—On sandy and gravelly soils, the broom, as a shrub, is found to predominate, particularly above freestone rock. Where the sand or gravel is of a calcareous nature, the whin acquires an establishment. The herbaceous plants peculiar to such soil are, bird's-foot trefoil, *Lotus corniculatus,* blue bell flower, *Campanula rotundifolia,* eye-bright, *Euphrasia officinalis,* sweet-scented spring grass, *Anthoxanthum odoratum,* and seaside sandwort, *Arenaria peploides.* When sandy soils in tillage receive too much of the harrow, the common spurry often destroys the growing crop. The common couch-grass, *Triticum repens,* is a troublesome plant, and requires close attention to the cleaning of drill crops to keep it under. The annual plants found amongst the corn, under proper cultivation, are, common spurry, *Spergula arvensis,* purple dead nettle, *Lamium purpureum,* common fumitory, *Fumaria officinalis,* shepherd's purse, *Thlaspi bursa-pastoris,* common knawel, *Scleranthus annuus,* thyme-leaved sandwort, *Arenaria serpyllifolia,* and common cudweed, *Gnaphalium germanicum.* Soil of this description is improved by lying long in pasture, and by eating turnips off it with sheep.—Moor may include heath-pastures in general, containing a considerable proportion of peat in the soil, with the subsoil exceedingly various, as indicated by the plants found. Many of the plants formerly mentioned are to be met with in low moors; and when the whin,

the ragwort, the *Lotus corniculatus*, the *Orobus tuberosus*, and the *Viola móntana*, are found to predominate in moor-grounds, though these plants are mixed with heath, the ground, if stones or steepness prevent not, may be improved by cultivation; but where the heath is found mixed with rein-deer moss, and the plants above specified absent, the soil and subsoil is sterile, and will not pay the expense of culture, and might be planted with the larch and Scotch fir to afford shelter and materials for fences to the neighbouring grounds. The following plants in moors indicate a wet retentive subsoil,—dwarf silky willow, *Salix repens*, butterwort, *Pinguicula vulgaris*, round-fruited carex, *Carex pilulifera*, moss-bush, *Juncus squarrosus*, scaly-stalked club-rush, *Scirpus cæspitosus*, Lancashire narthecium, *Narthecium ossifragum*, and grass of Parnassus, *Parnassia palustris*. On dry moors, containing a considerable proportion of peat earth, are, needle or petty whin, *Genista anglica*, mat-grass, *Nardus stricta*, yellow mountain violet, *Viola lutea*, common tormentil, *Tormentilla officinalis*, and mountain cudweed, *Gnaphalium dioicum*. — Marshy soils are found in their natural state to produce ragged robin, *Lychnis flos-cuculi*, fringed buckbean, *Menyanthes trifoliata*, marsh marygold, *Caltha palustris*, brook-lime, *Veronica beccabunga*, marsh cinquefoil, *Comarum palustre*, and marsh bed-straw, *Galium uliginosum*. And near the sea, sea arrow-grass, *Triglochin maritimum*, sea-marsh grass, *Poa procumbens*, pale carex, *Carex pallescens*, and great common carex, *Carex riparia*. When such marshes are dried, as they frequently contain a large proportion of decayed aquatic plants, they prove highly fertile, and few weeds appear after they are broken up. The most troublesome to farmers, are such as are introduced amongst seed grain, as goosegrass, *Galium aparine*. When the marsh is incumbent on marl, the common colt's-foot, *Tussilago farfara*, and the common butter bur, *Tussilago petasites*, are not easily rooted out. It may be remarked, that these plants are so partial to calcareous soils, as to form a signal to the natives of the lower valleys of Switzerland where to sink for marl.—Peat, or what is provincially termed moss, is often found without many plants covering the surface. Where the surface is dry, the cross-leaved heath, *Erica tetralix*, and the *Agrostis canina*, acquire an establishment. In the hollows are found, cotton grass, *Eriophorum polystachion*, and orange berry, *Vaccinium oxycoccus*. When moss is reduced to a state of cultivation by draining, the annual plants appearing are, soft brome grass, *Bromus mollis*, field scorpion grass, *Myosotis arvensis*, and wild oats, *Avena fatua*, and the *Galium aparine*, when its seeds are introduced amongst oats or barley seeds.—In the dens wholly inaccessible to the plough, and which are intended for plantations, the following plants, the natural productions of such dens, may assist in selecting suitable trees to the soil:—Where the great brake or fern, *Pteris aquilina*, is found in abundance, the oak will be found to succeed. The great wood rush, *Luzula maxima*, and the herb Paris, *Paris quadrifolia*, delight in tenacious soils, suitable to the hazel and the elm. The red campion, *Lychnis dioica*, the pilewort, *Ranunculus ficaria*, the dog's mercury, *Mercurialis perennis*, indicate a good soil for the maple and the ash. The wood anemone, *Anemone nemorum*, grows on a soil suitable to the birch. The water avens, *Geum rivale*, and the *Geranium pratense*, are found by the sides of rills, where the alder and Huntingdon willow will acquire a rapid growth.

The Improving of Soils.—The bringing of waste or barren lands into a state of cultivation is effected in various ways, according to the nature of the soil, the facilities of the situation, and the resources and objects of the reclaimer; and it is discussed in some of its most important bearings, in the articles Improvement of Land, Heath-Lands, Waste Lands, and Bogs. The ameliorating of the herbage and the increasing of the luxuriance of grass lands are accomplished by methods specially adapted to soil and circumstances; and are discussed in the articles Grass Lands, Meadow, Pasture, and Irrigation. The reclaiming and ameliorating of all sorts of wet lands, whether waste, grass, or arable, by the abduction of their excess of moisture, either along the surface or by taps or by subsoil ducts, are fully discussed in the article Draining. The neutralizing of acidity and of noxious oxides, the reduction of inert vegetable matter, the accelerating of the decomposition of stubborn organic manures, and the resolving and recombining of some mineral substances into available food for plants, by means of the well-known practice of liming, are discussed in the article Lime. The correcting of an excess of one chief mineral constituent by the intermixing of another, and the restoring or enriching of exhausted soils by the addition of plant-feeding substances in which they have become deficient, are discussed in the article Manure. The prompt removal of a great excess of coarse vegetable matter, or rather the prompt conversion of it into manurial principles, together with a concomitant ameliorating of the texture of the land which it has encumbered, is discussed in the article Paring and Burning. The artificial obtaining of an entirely new soil, in the form of a fresh deposit of alluvium, on low-lying lands, by the side and beneath the flood-level of rivers and estuaries, is discussed in the articles Colmata and Warping. The deepening of arable soils, the increasing of their porosity, and the renovating of their substance by means of additions or inversions from below, are discussed in the articles Trenching and Subsoil-Ploughing. The removing of foulness from arable lands, the accelerating of their mineral reduction, the full exposing of them to the chemical actions of the weather, and the seasonal subjecting of them to the completest possible course of tillage, are discussed in the article Fallow. And the ordinary and current conservation and increase of the fertility of arable lands, by the best routine practices of tillage and culture, are discussed in the articles Ploughing, Drill-Husbandry, Hoe, Horse-Hoe, Harrow, and Grubber, and in the articles on all the principal field crops.

The Cultivation of Soils.—Any soil, in order to be suitable for cultivation, or to possess the requisites of fertility, must contain all the mineral matters which yield the ashes of the plants destined to be cultivated upon it, in such a condition as to be available by the plants, and in sufficient quantity to enable the supply to be kept up by some economical mode of cultivation; it must consist of a due admixture of impalpable matter, and larger sized particles, so that it may be

porous and easily permeable by air and moisture, while, at the same time, there is a sufficient supply of matter in a state capable of undergoing chemical changes; and it must have mingled with it a sufficient supply of organic matter, in a state capable of decomposition by the action of air and water. To be fit for profitable cultivation, it must be free from any mineral substance which is destructive of fertility; it must be capable of being reduced to a sufficiently fine tilth, without an undue amount of labour; it must either be naturally capable of letting off any excess of water which may fall upon it, or capable of being made to do so artificially by draining; it must possess a structure which will allow the decomposition of organic matter mingled with it to proceed at a regular rate, being neither so fast as to waste the manure, nor so slow as to keep it too long fresh; and its situation must be such as to admit of all the operations of husbandry being performed in a proper manner, without occupying too much time, and must have a climate which shall give full promise of the plants arriving at perfection. To be capable of continued cropping, it must be ploughed and harrowed, and subjected to any other operations which may be necessary for thorough cleaning and pulverization; it must have its supply of organic matter, and part also of its mineral ingredients, renewed by returning to it from time to time in the shape of manure, what has been removed in the form of crops; and it must be kept in an active state, by having fermenting substances added to it at certain periods. And if it be in a bad or comparatively unproductive condition, then, in order to be freed from any great natural faults which hinder or impair its fertility, or to acquire such addition of new powers or increase of old ones as shall materially enhance its productiveness, or to recover the possession of any aggregate powers which it may have lost by overcropping or maltreatment, it must undergo either draining, liming, trenching, subsoil-ploughing, bare-fallowing, paring and burning, change of texture by intermixture of mineral manure, or whatever other of the operations mentioned in the preceding section, or of any two or more of them, may be best suited to improve it.

The comparative effects of vegetation upon soil in its natural or totally neglected condition, and in a condition of cultivation, may be stated as follows:—Uncultivated soil, however rich, becomes gradually less and less fertile, until it has attained the condition either of moor or marsh; it retains its luxuriance for the greatest length of time, when covered with forest trees and other large vegetables; it produces successive crops of different kinds, or, in other words, maintains a sort of natural rotation; when any species of plant on it disappears, its place is supplied by one of less value as an article of food, so that the richest pasture comes in time to produce only the coarsest and most worthless species of grass; and yet, though the natural produce of uncultivated soil thus uniformly decreases in value, the soil itself becomes progressively richer, so that, when brought under the plough, it will yield much larger returns than could be expected from its spontaneous produce. Soil which is regularly cultivated or continually ploughed yields its nourishment in much greater abundance, and with greater ease, to plants growing upon its surface; the facility with which the productive powers of well cultivated land are diminished, depends on its organized matter being more easily converted into compounds soluble in air and water; the decrease of fertility in carelessly cultivated soil depends, in addition to the above circumstance, upon a diminution in the proportion of its impalpable matter; cultivated land, when properly taken care of, becomes gradually richer and richer, notwithstanding the increased quantity of produce annually removed from it; if the same plant be cultivated for several years successively upon the same spot, the soil much more rapidly decreases in fertility than when a variety is kept up; and some of the most valuable mineral constituents of soil decrease in greater rapidity in proportion to the greater care bestowed upon its cultivation, altogether independent of the portions removed by the crops.

The particular principles involved in the successful cultivation of the numerous and widely different kinds of field crops, may, in a main degree, be deduced by intelligent farmers from the five following facts:—1. All plants require a good supply of nourishment during the first periods of their growth, for without this they will never arrive at perfection. If, therefore, nature has not provided a stock of nourishment laid up in the seed, it must be supplied artificially. Seeds, therefore, which are devoid of this natural supply of food, must be provided with an abundance of well fermented manure, unless it is required that the first stages of their development should occupy a considerable period of time. 2. Many plants have more than one method of propagating themselves; if, therefore, one method is more desired than another, means should be used to prevent the others from being accomplished, as by preventing the one, you increase the vigour of the other. 3. Plants lay up a store of nourishment for the next year, either in the wood, as in perennials, or in the seeds, as in annuals. 4. The starch of plants is always contained in cells, formed of a substance containing azote; and, consequently, there exists a fixed proportion between the quantity of azote composing the cells, and the amount of starch contained in them; hence it follows, that to increase the quantity of starch in a plant, you must increase its supply of azote, although starch itself contains no trace of this element. 5. In all parts of a plant there is an exact proportion between the various elements entering into its composition, so that an addition to one of them

is necessarily followed by a relative addition to them all. If, for example, a plant possesses one part containing 2 grains of azote, combined with 18 grains of other elements, and another portion containing 2 grains of azote, combined with 48 grains of other elements; if we, by any means, prevent the development of the more highly azotised portion, viz., the 2 to 18, we shall produce a proportional increase in the other; so that, by preventing the formation of 20 grains of the highly azotised portion, we obtain 50 grains of that which contains proportionally less azote.

The Analysis of Soils.—The meanings of the word analysis, a brief general view of the importance of the analysis of soils, and a detailed account of the principles of all chemical analysis, are given in the article ANALYSIS; and a number of statements and discussions which have a strong bearing on questions as to the methods and uses of analysis of soils occur in the articles MANURE, FARM-YARD MANURE, GUANO, FOOD OF PLANTS, and many others. The analysing of soils affords more certain and more valuable information respecting them than any other mode of investigation, and is essential for opening a balance-account between the withdrawal of substances by crops and the adding of them in manures, and forms a chief means of reducing the general doctrines and discoveries of agricultural chemistry to beneficial practice, and in general serves as a mighty appliance for carrying forward in the world, and fixing down on individual farms, the great and growing agricultural intelligence of the age. Two kinds of it may be practised, the mechanical and the chemical; and excellent methods of these—the mechanical by the Rev. W. L. Rham, and the chemical by Dr. Ure—have been published in the Journals of the Royal Agricultural Society, and shall here be transcribed.

"The soil to be examined must be taken a few inches under the surface, and in different parts of a field. If there appears much uniformity, the portions may be mixed, in order to have the average quality of the soil: should there be a visible difference between one portion and another, which is often the case, each may be analysed separately. A portion of the earth to be analysed is dried in the sun or near a fire, until it feels quite dry in the hand. It is then reduced to powder by the fingers, or by rolling it on a deal board with a wooden roller, so as to separate the particles, but not to grind them: any small stones above the size of a pea must be taken out. If these form a considerable part of the soil, their proportion must be ascertained by weight; their nature and quality may be afterwards examined. This, being a very simple operation, and obvious to the sight, need not be described. Where the stones and pebbles are evidently accidental, they may be overlooked, as having little influence on the fertility. The dry earth, cleared from stones, should be accurately weighed; and it is convenient to take some determined quantity of grains, as 1,000, 500, or 250, according to the accuracy of the instruments at hand. This portion should be put into a shallow earthen or metal vessel, and heated over the fire, or a lamp, for about ten minutes, stirring it with a chip of dry wood: the heat should not be so great as to discolour the wood. It may then be allowed to cool, and be weighed again; the loss of weight indicates the water which remained uncombined after the soil appeared quite dry. This is the first thing to be noted. The power of retaining water, without any external appearance of moisture, is greatest in humus, next in clay, both of which readily absorb it from the atmosphere; carbonate of lime does so in a less degree, and siliceous sand least of all. This moisture occupies the pores of the soil, and is very different from the water which is combined with clay as a part of its substance, and to which it owes its ductility; for when this last is expelled by a great heat, the clay loses its quality, and approaches to the nature of sand. Pounded brick will not bind with water; and porcelain reduced to a fine powder has all the properties of siliceous sand in the soil. The finer the division of the particles of the soil, the greater will be its power of absorbing and retaining water; but in a soil where clay greatly predominates, the lumps sometimes become so hard and baked by the sun that the moisture cannot penetrate, and in this case the power of absorption is much diminished. Hence loams in which there is a good proportion of humus have a greater power of absorption than the pure earths. Taking all circumstances into consideration, it will be found that the soils which most readily absorb moisture are also the most fertile, and therefore it is important to ascertain their power of absorption. This can be found by comparison. Equal portions of different soils, dried as before, are placed in the opposite scales of a good balance, and left exposed for some time to a moist atmosphere. That which preponderates has the greatest power of absorption; the degree is measured by the difference of the acquired weights.

"Another important circumstance is the specific gravity of a soil. The different earths have very different specific gravities; and humus being lighter than any mineral earth, the lightness of the soil is a sure indication of its richness, excepting where this lightness is occasioned by an excess of undecomposed vegetable matter, or peat. Humus, when nearly pure, has a specific gravity varying from 1·2 to 1·5; fine porcelain-clay, 2; chalk, about 2·3; siliceous sand from 2·5 to 2·7. Mixed soils have specific gravities varying according to the proportions of their component parts. Those in which clay, chalk, and humus abound, and which are generally the most fertile, are the lightest. The sandy soils are heavier, and the more so if they contain oxides of iron or of other metals; and it is well known that the ferruginous sands are the most barren. The common expression of *light*, when applied to a sandy soil, has no reference to its specific gravity, but merely to the force required to plough it. No carrier would say that a loose sandy road was a light one. The easiest and readiest method of determining the specific gravity of earth, or any substance which is of a loose texture, is that described by Dr. Ure in his Philosophy of Manufactures (page 97), as employed by him to ascertain the specific gravities of cotton, wool, silk, and flax. It is as follows:—Take a narrow-necked phial capable of holding four or five ounces of water; mark a line round the middle of the neck with the point of a diamond or a file; fill the phial up to the mark with river or rain water, and poise it with sand or any other substance in a scale; then put 1,000 grains' weight in the same scale with the phial, and pour out water till the equilibrium is restored. In the vacant space, which is evidently equal to the bulk of 1,000 grains of water, introduce the soil till the water rises to the mark in the neck. Then put into the opposite scale grain weights sufficient to restore the equilibrium. The number of grains required for this purpose will

denote the specific gravity of the soil compared to water as 1,000. Suppose, for example, that siliceous sand, which is 2·7 times denser than water, is poured into the vacant space, it will require 2,700 grains to fill the space occupied by the 1,000 grains of water; and thus we have the specific gravity without any calculation. If instead of 1,000 grains, we use only 500, or 250, the result will be the same, if we multiply the grains in the other scale by 2 or 4. We will give a few examples of soils of which the specific gravity has been carefully determined.

A rich garden soil, which contained per cent.,

Clay	52·4
Siliceous Sand	36·5
Calcareous Sand	1·8
Carbonate of Lime	2·0
Humus	7·3

had a specific gravity of 2·332.

A good loam, consisting of

Clay	51·2
Siliceous Sand	42 7
Calcareous Sand	0·4
Carbonate of Lime	2·3
Humus	3·4

had a specific gravity of 2·401.

A poorer soil, of which the component parts were

Siliceous Sand	64·0
Clay	32·3
Calcareous Sand	1·2
Carbonate of Lime	1·2
Humus	1·3

had a specific gravity of 2·526. These examples suffice to show that the specific gravity of a soil is some tolerable indication of its fertility. It cannot, however, be entirely relied upon in the absence of other proofs; for there may be many different mixtures of earths which will have the same specific gravity, although they may differ greatly in their fertility; but it will facilitate the analysis, and often detect mistakes in the process, if the result does not accord with the specific gravity found.

"We proceed now to the analysis. The portion of soil which has been deprived of all its water, as described above, must be sifted through metallic sieves of different fineness. The first is made of a perforated tin plate, the holes of which are about one-twentieth of an inch in diameter. Whatever does not go through this is put by. The remainder is successively passed through two or three more sieves, increasing in fineness to the last, which is of the finest wire-cloth, having from 150 to 170 threads in an inch: whatever passes through this is impalpable powder. Thus we have already a division of the soil according to the size of its particles:—1st, the coarse grit left in the first sieve; 2d, the finer grit in No. 2; 3d, fine sand in No. 3; and 4th, impalpable powder, which has passed through the last sieve. To facilitate this part of the operation the sieves may be made so as to fit into one another, like the filterers in a coffee-biggin, the last fitting into a tin pot which will hold about a pint of water: a cover being made to fit on the top sieve, the instrument is complete. (See *Fig.*) Thus all the sifting may be done at once, without any loss. Any lumps which are not thoroughly pulverised must be broken. The coarser sand left in the sieve No. 1 must now be washed with pure water to detach any fine dust adhering to it; what runs through may be used to wash No. 2, in the same manner, and then may pass through No. 3 to the impalpable matter which passed through all the sieves. A sufficient quantity of water must be used to render the whole of this last nearly fluid. There will then be three different portions of the washed soil left in the sieves, and a portion of impalpable matter diffused through the water in the lower division of the instrument. This last is the principal object of analysis, and that to which Sir Humphrey Davy usually confined his attention, merely noticing the proportion of coarser sand in the soil. It contains, no doubt, the great principle of fertility and nutrition; and the effect of the coarser parts may be considered as chiefly mechanical. But they may much affect the fertility of the finer parts, and are of the greatest importance to the soil in which they are blended: they consequently deserve a more minute examination, to which we will return. In the mean time our attention shall be directed to the composition of the finer earth in No. 4, which is mixed with water in a semi-fluid state. This is well shaken, and suddenly poured into a deep glass vessel, and allowed to settle for a few minutes, when the heavier earth, which is sand, will be deposited, and the lighter may be poured off suspended in the water. It requires some little practice to effect this at once, but a few trials will soon enable any one to do it. This operation may be repeated until all the sand, of which the particles are visible to the naked eye, is separated. The earth and water decanted out of this last vessel are now poured into a glass tube, 18 inches long (No. 1), the bore of which is less than an inch: one end is stopped with a cork fitted into it, and the other has a small lip for the convenience of pouring out the contents. In a short time there will be a further deposition of earth, which will be principally alumina. What remains suspended in the water over it is gently poured off into another similar tube (No. 2): this will contain nearly the whole of the humus, which will take some hours to be deposited in the form of a fine brown mud. The contents of the tube No. 1 may now have a little more water added to them; after being well shaken, the tube may be set upright, and left for half an hour to settle: what remains suspended in the water after this must be added to the humus in the tube No. 2. After some time this will also be deposited; and the clear water may be decanted off. The mud which remains is put on filtering-paper in a glass funnel, and, when all the water has drained from it, it is dried over the fire, and weighed. This is the most important portion of the soil. The fine earths deposited in the tube No. 1 will consist of very fine particles of sand, clay, and perhaps carbonate of lime. The sand will appear deposited in the bottom of the tube. The clay may be easily diffused in the water above it by stirring it carefully with a small rod without reaching the sand. It may then be decanted off with the water into another tube (No. 3), and allowed to settle: this part of the operation may be carried to a great degree of perfection by great care, and by examining the results occasionally with a small microscope; but for all common practical purposes, it is sufficient to separate the vegetable earth from the mineral, and the visible particles of sand from the finer. The contents of No. 1 having been collected, as well as those of No. 3, are dried over the fire and accurately weighed. The same is done with the earths which remain on the sieves. All the water in which the earths have been diffused and washed is collected and passed through filtering-paper, and then set over the fire in a common saucepan. It is boiled away gently until it is reduced to a small portion, which begins to look turbid. The complete evaporation is finished in an evaporating dish, as slowly as possible, and the residue is the soluble matter contained in the soil. It will be sufficient to dry and weigh this, as its further analysis would require more skill and chemical knowledge

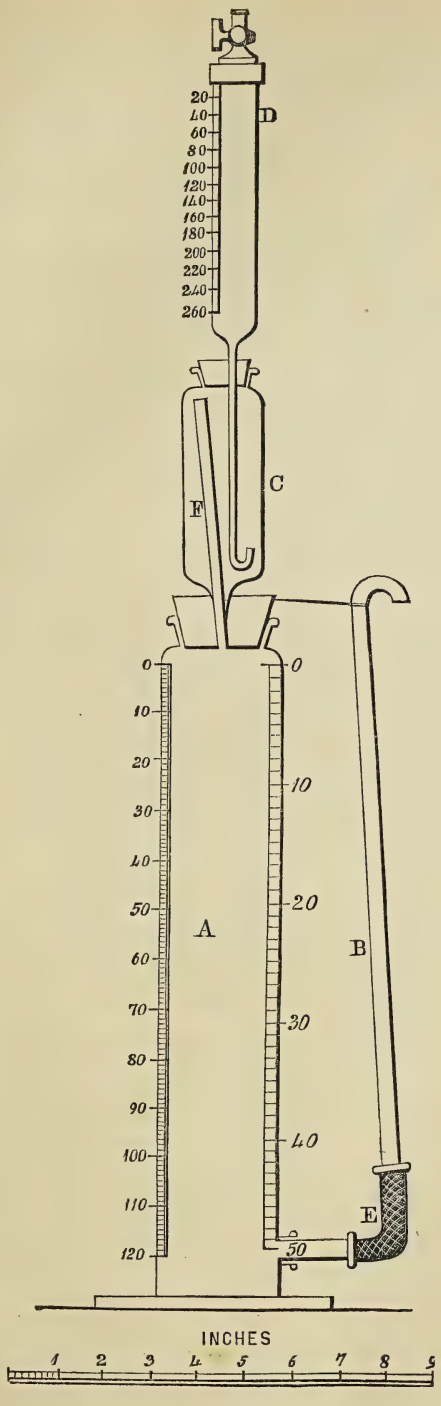
than we suppose in the operator. Salts may be detected by the taste, or by the crystals formed in the evaporation; but, unless there is a decided saline taste, the whole may be considered as soluble humus, and the immediate fertility of the soil depends greatly on the quantity of it. To recapitulate what has been obtained, — we shall have the coarse grit in sieve No. 1; the sand in Nos. 2 and 3; the fine earth separated in the tubes Nos. 1 and 3; the humus in tube No. 2 and on the filtering-paper; and the soluble parts in the evaporating-dish. All these substances must be well dried over the fire, as was done with the soil at first, and each separate part accurately weighed. The sum of them ought to be equal to the original portion of soil subjected to analysis after the water was driven off; but there always is a loss, even with the most experienced analyser. This loss will be principally in the finer parts, which are dissipated in the operation.

"But the analysis is not yet completed: we have separated the sand, clay, and humus; but there may be a portion of carbonate of lime, in the form of sand, or of finely-divided earth mixed with the other earths. To ascertain this, each portion, excepting the humus, is put into a separate cup, and a little muriatic acid, diluted with four times its weight of water, is poured on it. If there is any effervescence, it shows the presence of carbonate of lime; diluted acid is then added gradually, as long as the effervescence is renewed by the addition. When this ceases, and the water continues to have an acid taste, more pure water is added, and each portion separately filtered, dried, and weighed. The loss of weight in each gives the quantities of carbonate of lime dissolved by the muriatic acid, and which has passed with the water in the form of muriate of lime.* The different weights being now collected, the result of the operations might be set down. There may be many mineral substances in the soil which this mode of analysing will not detect; and some of these may materially affect the fertility. In most cases there will be something to indicate the presence of metals. Iron abounds in most soils: when the quantity is considerable, it will be detected by pouring a decoction of gall-nuts into the water which has washed the earth; it will immediately become of a bluish dark colour. The other metals are not of frequent occurrence. Sulphate of lime or gypsum, and also magnesia, are found in some soils; but the separation of them can only be effected by those who are well acquainted with chemistry: they fortunately occur very seldom, and the places where they are found are generally well known. For all practical purposes, it is sufficient to ascertain the proportion of sand, clay, carbonate of lime, and humus which any soil contains. Many soils which have been highly manured contain portions of undecomposed vegetable substances, and fibres of roots; these will be found mixed with the coarser earths separated by the sifting: not being a part of the natural soil, they need not be taken into the account; but they may be separated by washing the earths, as they are much lighter, and will come over in the first decantations. They may be dried and weighed, and the quantity set down in the result, if it is desirable. Some very barren sands, containing very little argillaceous earth or humus, may readily be known by the copious sandy deposit which they rapidly make when diffused through water. Good natural loams are not so easily judged of; but the preceding mode of analysis will in general detect their intrinsic value. When a soil contains peaty matter, it is easily discovered by the irregular black particles which are visible in it. Peat differs from humus only in being in a different state of decomposition, and containing a considerable portion of tannin; when acted upon by lime or alkalies, and brought into a state of greater decomposition, it is not to be distinguished from humus in its qualities.

"The process which we have described, simple as it is, may yet be too tedious for the farmer who is desirous of speedily comparing different soils; and we will indicate a still simpler method of ascertaining, nearly, the composition of a soil and a simple instrument by which it may be done. Take a glass tube, $\frac{3}{4}$ of an inch in internal diameter, and 3 feet long; fit a cork into one end, and set it upright; fill it half full of pure water; take nearly as much water as has been poured into the tube; and mix with it the portion of soil which is to be examined, in quantity not more than will occupy 6 inches of the tube; pour the mixture rapidly into the tube, and let it stand in a corner of a room, or supported upright in any way. In half-an-hour it may be examined. The earths will have been deposited according to the size and specific gravity of their particles. The portion still suspended in the water may be allowed to settle; and there will appear in the tube layers of sand, clay, and humus, which may be measured by a scale, and thus the proportions nearly ascertained. When a farmer is about to hire a farm, of which the quality is not well known to him, he may be much assisted in his judgment by this simple experiment, if he has no time or opportunity for a more accurate analysis. For the glass tube may be substituted one of tin or zinc 2 feet in length, with a piece of glass tube, a foot long, joined to it by means of a brass collar or ferule with a screw cut in it, which is cemented to the glass, and screws on the metal tube; and thus the instrument may be made more portable. When the water has been poured off, and the earths only remain, the cork may be taken out, and the contents pushed out on a plate, by means of a rod and a plug which exactly fits the internal diameter of the tube. They may thus be more particularly examined."

"The first problem in an agricultural analysis," says Dr. Ure, "is to find the proportion of calcareous matter, as carbonate and phosphate of lime. This may be easily solved with the aid of the instrument figured below, which may be called the Limestone Meter. A, is a cylinder of glass, two inches in diameter, and fourteen inches long, graduated on one side with a scale, into spaces of 100 water-grain measures from 0 to 12,000, marked 10, 20, 30, &c.; and graduated on the other side into spaces of 240 water-grain measure, each. The former scale is used for the analysis of all sorts of alkaline carbonates, and also of acids; the latter is adapted to the direct analysis of carbonate of lime and marls, and indirectly to that of phosphate of lime and carbonate of magnesia. The cylinder A, has a tubulure in its side near to the bottom; this is closed with a cork, in the axis of which a short glass tube is cemented, hooped externally to a collar of caoutchouc E, which serves as a joint to the upright long glass tube B, held near its upper recurved end in a hooked wire. The top of the cylinder A is closed with an elastic cork, through a perforation in which the taper tail of the little phial C passes air-tight. The small tube F, open at both its ends, is cemented on its outer surface, into the bottom of the phial C, so as to close it, while the tube itself opens a free passage to gas, from the shoulder of the phial, down into the cylinder A. The mouth of the phial C is shut with a cork, through which the small end of the tube D passes air-tight. The tube D is graduated into spaces of 10, 20, &c., water-grain mea-

* It may be objected to this mode of ascertaining the carbonate of lime, that the muriatic acid will dissolve iron, and a portion, however small, of alumina as well as carbonate of lime, and that the collecting the carbonic acid evolved is a more exact measure of the quantities of the carbonate. This may be admitted; but we repeat that we only propose a simple and easy analysis, which will approximate to the truth, and not by any means a perfect one.



sures up to 250, and is closed at top with a stop-cock. Its lower and capillary extremity is recurved. In ascertaining with this instrument the proportion of real carbonate of lime, in any limestone, marl, or soil, proceed as follows:—Lift out the phial C, and pour water into the cylinder A till it stands about half an inch below the line marked 0, and fill up this space with common linseed-oil. Restore the phial C to its place, pressing it in air-tight. Then take out its cork with its graduated tube, and introduce into the phial as many grains' weight of the soil or marl as it is proper to operate upon. Of an average limestone 50 grains are sufficient, because the magnified scale of the *lime-proof* is adapted to the analysis of 50 grains of pure carbonate of lime. Of soils and marls, 100, 200, or even 500 grains, may be taken, because these substances will rarely contain one-tenth their weight of carbonate of lime. But as the result may always be obtained within five minutes, at the cost of half a farthing, several successive experiments may be made on different weights of the sample. Having introduced the proper weight of the object into the phial, cover it with water, till this stands a little above the point to which the recurved tube descends. Holding D in the hand, dip its bent point into a phial containing ordinary muriatic (hydrochloric) acid, diluted with its own bulk of water, and applying the mouth to the opened stop-cock, suck up the acid into the tube till this be about two-thirds full, then turn the key of the cock before it is taken from the lips, and the acid will not drop out when the tube is held upright. Replace the cork with its tube D in the phial C. Detach the long tube, B, from its wire-rest with the left hand, and hold its curved extremity above an empty basin; then with the right hand open the stop-cock of D, to let a little acid run down upon the marl, but shut it almost instantly again, lest too much acid should escape, and cause so brisk an effervescence as to occasion an overflow of the mixture into the small tube, F. The disengaged carbonic acid escapes through the tube F, presses on the surface of the oil in A, and causes a stream of water to flow from the tube B, into the subjacent basin. When the water ceases to run, open the stop-cock again, when more acid will descend, cause a fresh extrication of gas, and a further flow of water. The curved end of the tube B should be progressively lowered, as the oil falls in A, so as to maintain its level and that in the tube in the same horizontal plane. Whenever gas ceases to be extricated by the muriatic acid, the experiment is completed, and the number on the *lime-meter* scale opposite to the upper surface of the oil, denotes the number of grains of carbonate of lime, in the quantity of limestone, marl, or soil, put into the phial C for experiment. A little carbonic acid gas remains condensed in the muriatic solution, but this is not more than equivalent to the bulk of liquid acid introduced into the capacity of the apparatus; so that no compensation need be made in this account. For the purpose of minute chemical research, that portion of gas may be expelled by surrounding the phial C with a cloth wrung out of hot water, and the volume of dilute acid added, may also be taken into the account. Thus the composition of carbonates by an acid, and of acids by a bicarbonate, may be determined by means of this instrument with equal rapidity and precision. The contents of the phial may be poured out into a porcelain capsule, gently heated, and thrown on a filter. The lime of the carbonate, as well as the phosphate of lime and the magnesia, will pass through in solution along with a very little iron. On super-saturating the acidulous liquor with water of pure ammonia, phosphate of lime (if present) will fall, and may be drained on a filter and dried. Taken off the dried filter, and digested with a little dilute sulphuric acid, sulphate of lime will result, characterized by its entire insolubility in dilute alcohol. Hence the sulphate washed with vinous spirits, dried and calcined, will represent by its weight one-fifth more than the original weight of the phosphate. By the action of the sulphuric acid, the iron precipitated by the ammonia with the phosphate is got rid of. The magnesia, unless its proportion had been very great, will all remain dis-

solved as ammonia-muriate, and its quantity may be ascertained by precipitating it either with soda or phosphate of soda. In the former case, the substance obtained when washed on a filter, dried and ignited, is pure magnesia; in the latter, it is the ammonia-phosphate of magnesia, and when dried at the moderate heat of 120° Fahr., it represents by its weight about six times of the magnesia present; or for 100 parts, 16½ of magnesia.

"When a complete analysis of a soil is to be made, the following apparatus is convenient:—A large glass flask, or matrass, with a sucked-in or concave thin bottom. This should hold at least a quart of water; and when the soil and dilute acid are introduced, it is to be placed on a stand over the gentle flame of a spirit lamp, while the beak of a large glass funnel, having its mouth covered with a porcelain basin, filled with cold water, is inserted into the neck of a flask. By this arrangement, a continual ebullition may be maintained in the mixture of soil and acid, without loss of acid, or nuisance from its fumes, because the vapours are condensed whenever they reach the cold basin above the funnel, and a perpetual cohobation takes place. A boiling heat may be kept up in this way till every constituent of the soil, except the silica, becomes dissolved. Muriatic acid is generally preferred for the analysis of soils, and in somewhat greater quantity than the bases in the given weight of soil can neutralise. The funnel and porcelain basin should be properly supported upon the rings of the chemical stand. I generally subject 100 grains of soil to the action of boiling dilute acid in this way for 6 or 8 hours; at the end of that period, I throw the contents of the matrass upon a filter, and super-saturate the filtered liquid with ammonia. The silica which remains on the filter having been washed in the process, is dried, ignited, and weighed. The alumina, iron-oxide, and phosphate of lime, thrown down by the ammonia, being washed in the filter, and dried to a cheesy consistence, are removed with a bone or tortoise-shell blade into a silver basin, and digested with heat in a solution of pure potash, whereby the alumina is dissolved, when its alkaline solution is to be passed through a filter, then saturated with muriatic acid, and next super-saturated with ammonia. Pure white alumina falls, which is to be separated on a filter, washed, dried, ignited, and weighed. The iron and phosphate of lime on the alkaline filter may be dried, gently ignited, and weighed, or otherwise directly separated from each other without that step, by the action of dilute alcohol, acidulated with sulphuric acid, at a gentle heat. Thus the iron-oxide will be dissolved, and its solution may be passed through a filter, while the sulphate of lime will remain upon it, to be dried, ignited, and weighed. Five parts of it correspond to four of phosphate. The iron is obtained by precipitation with water of ammonia, filtration, and ignition. The first filtered liquor, with excess of ammonia, contains the lime of the carbonate, and the magnesia. The former is separated by a solution of oxalate of ammonia, with digestion in a gentle warmth for a few hours, filtration, and very gentle ignition of the washed dry powder, when the pure carbonate of lime is obtained. The magnesia, existing in the filtered liquor as an ammonia-muriate, may be obtained by precipitation with soda, or phosphate of soda, as already described. For some refractory soils, in which the alumina exists as a double or triple silicate, it becomes necessary to fuse 50 grains of the sample, in fine powder, mixed with four times its weight of dry carbonate of soda, the mixture being put into a platinum crucible, and into a cavity in its centre, 50 grains of hydrate of potash being laid. The crucible being slowly raised to a red-white heat, affords a fused liquid quite homogeneous, of a grey or brown colour, according to the metals present in it. Manganese gives a purple tint; and iron a reddish brown. The fused matter should be poured out into a shallow platinum basin; and, whenever it cools, it should be pulverized, dissolved in dilute muriatic acid, the solution evaporated to dryness, the dry mass again digested in hot water, acidulated with muriatic acid, and the whole thrown upon a filter. Pure silica will remain on the filter, to be washed, dried, ignited, and weighed. The filtered liquor contains the remaining constituents of the soil, and is to be treated as already described.

"Besides these systematic investigations, researches may be made for certain peculiar substances, and especially the neutro-saline constituents. In this view 100 grains of the soil may be triturated with 20 times their weight of distilled water, placed in a beaker, till the clayey matter subsides, and the clear portion then be decanted into a filter. A little of the filtered liquor should be tested with nitrate of barytes, and also with oxalate of ammonia; and if each portion yields a precipitate, they show the presence of sulphate of lime; and the following steps ought to be taken to eliminate it entirely: 200 grains of the soil should be triturated with a quart of distilled water, holding 50 grains of sal-ammoniac, in solution. The mixture should be allowed to clarify itself by subsidence, when the supernatant clear liquor should be filtered, and evaporated down to 2 ounce measures, and then mixed with that bulk of strong whisky (11 per cent. overproof). The whole sulphate of lime will be now separated from the fluid, and after being drained on a filter, may be dried, ignited, and weighed. For determining the alkaline salts, the water filtered from the 100 grains of the soil should be evaporated down to one-fifth of its bulk, and then treated—1st, with nitrate of barytes for the sulphates; 2d, with nitrate of silver for the muriates; 3d, with oxalate of ammonia, for the nitrate or muriate of lime (provided no sulphate of lime is indicated by the first test); 4th, with litmus paper, for alkaline or acid reaction; 5th, with soda-chloride of platinum for potash salts, which are very valuable for the vigorous growth of many plants. The portion of soil tested for potash salts should, before being digested in water, be gently calcined, to insure the expulsion of every particle of ammoniacal salt, otherwise the precipitate afforded by soda-chloride of platinum would be fallacious.

"Another peculiar research of great importance is that which determines the amount of ammonia in a soil; and which may exist either ready formed, or in its elements, capable of affording a portion of the azotic food so indispensable to vigorous vegetation. The actual ammonia is easily obtained by distilling the soil along with some milk of lime. The distilled water will contain all the volatile alkali, which may be measured by the number of drops of a standard dilute acid, which it will saturate. The potential ammonia, slumbering, so to speak, in its embryo elements, may be estimated by igniting 200 grains of the soil with its own weight of a mixture of hydrate of soda and quicklime.

"Since the phosphates are such precious ingredients towards fertilizing soils, it is desirable to possess a clear and simple test of their presence. For this purpose, digest the soil, for an hour or so, with a moderate heat, in dilute nitric acid, free from muriatic (viz. which affords, when largely diluted, no precipitate, by the addition of a solution of nitrate of silver). Throw the mixture on a filter, and to the filtered liquid add potash-water, cautiously, till the instant that a precipitate begins to appear; then drop into it a weak solution of nitrate of silver. If any phosphoric salts be present, a yellowish precipitate will immediately fall, which is re-soluble in

an excess of nitric acid. Whatever is not thus dissolved is chloride of silver, and ought to be separated by filtration: on adding then weak water of potash (not ammonia) cautiously to the filtered liquid, the pure phosphate of silver will be obtained, without any alumina or iron, provided the liquid be still acidulous in a slight degree. It ought to be remembered that chloride of silver falls in a *white* curdy form, quite different from that of the phosphate of silver. The portion of soil used for this experiment should be fresh, and not calcined, because the *phosphates*, when ignited, afford white precipitates with salts of silver. The stronger the solution of the phosphoric saline compound is, the more characteristic is the yellow precipitate with silver; and then ammonia may be used for effecting the partial saturation of the acid excess. Sulphate of magnesia is an excellent re-agent for detecting phosphoric acid, and for separating it from the above acid solution, when it is partially neutralized with ammonia; for the magnesia forms, with the phosphoric acid and ammonia, the insoluble granular precipitate of ammonia-magnesian phosphate. A solution of sulphate of magnesia, containing a little sal-ammoniac, is probably the best test-liquor for detecting phosphates in faintly acidulous, but still better in neutral, solutions. In almost all soils of an arable nature under cultivation in this country, there is a sufficiency of calcareous matter present to counteract the combination of phosphoric acid with alumina or oxide of iron, for which reason it would be an idle refinement of agricultural analysis to search for phosphates of alumina and iron. As for manganese, often associated with iron, it exists in too small a proportion, and is possessed of too little value to make it worth while to effect its separation. It gives to calcined iron-oxide a black hue, and is characterized in its saline solutions by the flesh-coloured precipitate which it affords with hydro-sulphuret of ammonia, after the whole of the iron has been thrown down by boiling the solution of the two metals with pure carbonate of lime.

"The organic matter in any soil may be correctly estimated by calcining its powder pretty strongly till the carbonic acid be expelled from the lime in it. The loss of weight, deducting that due to the carbonic acid gas (which is known from an independent experiment), gives the quantity of organic matter. Its quality is determined by the ultimate analysis by means of hydrate of soda and quicklime, as previously stated."

SOILING. The feeding of live stock in summer with green food, cut daily, and given to them in houses, stalls, or yards. It is not suitable for young or growing animals, who require a moderate degree of exercise in the fields in order to the maintaining of health and vigour,—nor for most of the live stock of farms which are so extensive that the daily carrying of the green food from the comparatively distant fields would involve too great an expense; but it is well suited for the final feeding of cattle on all sufficiently convenient farms,—for the ordinary feeding of working horses and working oxen, whose time is too valuable to allow of their slowly grazing in the field,—for the feeding of hogs and other minor stock, who do harm by roaming abroad,—and for the feeding of milch cows on all small country farms, town dairy farms, and cottier's plots or allotments. "It is not very generally adopted in British husbandry," says Mr. Rham, "it being so much easier to allow the cattle to crop their food in the pastures; but in those countries where property in land is greatly subdivided, and where farms are small and good pasture scarce, as in Flanders, France, and Switzerland, especially where the vineyards render manure scarce and dear by taking a considerable portion of it and returning none, there the soiling of cattle is almost a matter of necessity. A cow or ox requires from two to three acres of pasture or meadow to feed it all the year round, allowing a portion for hay. But by raising clover, lucern, sainfoin, tares, and other green crops, three cows or more can be fed with the produce of one acre, especially if a portion is in turnips or other succulent roots. Thus the straw of the white crops is converted into excellent manure, and the land kept in a state of fertility." The system is admirably adapted to the existing state of the greater part of Ireland, and, if generally adopted, would materially assist to relieve the prevailing penury of the small farmers of that country; and it is also well suited to many middle-sized and even large farms in all parts of Britain, where the supplies of manure are scanty or costly, or where the circumstances of soil and situation would produce the highest profit from a maximum growth of corn,—and it could be sufficiently well accommodated to the carrying conveniences of any extensive farm to which it is otherwise eminently suitable, by the erection of houses or sheds for the cattle in different and mutually distant localities.

One advantage of soiling, is the addition to the health, strength, and secretions or flesh of the animals, resulting from regularity and fulness of feeding, from the absence of all interruption and inconvenience in feeding, and from superior protection from the heat of the sun and the harassing attacks of flies.—Another advantage is the economising of food, by the prevention of waste in the use of it, by the growing of kinds which are far bulkier and more nourishing than any crops of grass, and by the saving of land for the production of the costlier sorts of food suitable for the use of man. Any given superficies of land has been proved, by many, various, and careful experiments, to feed from two to five or six times more cattle in the soiling

method than in the depasturing one; and probably no one piece, if wisely managed, would ever do less than feed at least three or four times more, while many a piece might feed so much as seven or eight times. Waste often occurs also in the soiling method, indeed, by portions of leguminous crops getting into pod before being cut, by portions running into over-ripeness and decay, and by some part of the cut and carried supplies being trodden down or heated; but these modes of waste, as well as all others incidental to soiling, may easily be avoided by methodical proportioning of the different kinds of green crop, by timeously cutting down the excess of each for hay, and by proper system in the daily carrying and feeding; while the methods of waste and loss incidental to depasturing—such as the trampling down of the herbage, the defouling of it with excrements, and the total occupation of the land with it to the exclusion of bulky green crops and of all cereal ones—are inevitable and unmitigable. Even, too, in spite of waste needlessly incurred in soiling practices, and in spite also of clumsier and less economical methods of husbandry employed in raising the crops, the various trials recorded long ago in the Annals of Agriculture clearly demonstrate that a vastly greater number of stock may be kept upon the same extent of land by soiling than by depasturing.—But a third and even greater advantage is the obtaining of a comparatively vast quantity of excellent manure for the raising of rich crops on the additional lands made available for arable husbandry. In the depasturing system, the excrement of live stock contributes scarcely any thing in the way of fertilizement, being scattered about the fields and dissipated by strong exposure to the sunshine and the weather; or, on the whole, it is rather injurious than useful, blanching and burning the tender grass on the spots where it falls, and rendering them for a long time blank and practically barren. "But soiling with green food in summer is a method admirably calculated for producing an abundance of manure; as from the great increase in the urinary discharges in the consumption of green food in this way, and the heat of the season, the littering material, whatever it may be, is speedily converted into manure; by which means, with proper attention, vast stores of manure may consequently be raised, where there would otherwise be none. By these means the summer produce in manure may probably be made to exceed that of the winter, and at the same time be superior in quality, as there is reason to suppose, that the manure produced by any kind of cattle fed in the same way, when not in a state of fattening, is much better in the summer than in the winter season. The proportion of valuable manure that the careful farmer may be capable of providing by this system of management is scarcely to be conceived, except by those who have been in the practice. In this view it is of much importance to have reservoirs for the reception of the urine, in order that it may be occasionally thrown up over the litter, and thereby promote its more speedy conversion into manure."

In order to ensure the full benefits of soiling, the farmer who practises it must pay strict attention to the circumstances connected with it, —particularly to having convenient sheds and yards, to the providing of suitable crops in proper succession and in due proportion, to the orderly and regular cutting, carrying, and apportioning of the food, and to the full and constant supply of suitable materials for the purpose of litter. The sheds and yards, as to both relative position and internal arrangement, ought to be such as to economise labour in the feeding of the stock and in the making and accumulating of the manure. The crops raised should be so selected and proportioned as, in the aggregate, to afford a constant and steady supply of green food from the beginning of spring till the end of autumn. Rye and winter barley, sown early in autumn, will be ready for use in the earliest mild weather of spring; the same crops sown later with winter tares, and the young clover which was not cropped in autumn, will follow; the artificial grasses and the early-mown grass of water-meadows, will come next,—the latter modified and made palatable by intermixture of oats and cut-straw; and clover, spring tares from successions of sowings, and lucern and sainfoin on farms which have suitable soil for them, will fully and uninterruptedly maintain the supply till the commencement of winter-feeding. Other crops also, such as white mustard and succory, may be made to lend their aid. The supplies from the field to the feeding-place ought always to be fresh, regular, and exactly proportioned to the current wants of the stock. No food should be allowed to stand packed in the carts, or to be apportioned to the animals in large quantities at a time; for all is liable to pass rapidly into a state of incipient fermentation, and to become disagreeable and be rejected. The animals, too, thrive best by receiving their food in small quantities, at short intervals, and always in a perfectly fresh condition; and they ought, in every instance, to be fed at least three times a-day, and may with advantage be fed four times. Litter ought always to be supplied in abundance; and wherever sufficient provision cannot be made for it in the form of straw, stores ought to be laid up of ferns, rushes, forest leaves, and any other similar materials which can be found. Care ought also to be constantly practised that the sheds and yards be kept well ventilated, that the cribs, racks, and other feeding spots be kept perfectly clean, that the bodies of the animals be kept free from all sorts of dirt, that a plentiful supply of pure water be maintained in a situation of constant access to the animals, that the kinds of food be occasionally varied and always agreeable,

and that the animals be turned out into the open air during a few hours in the cool of the evening in summer, and in the middle of the day when the season advances.

SOILS (Analysis of). See Soil.

SOJA. An annual, tropical, culinary plant, of the vetch division of the leguminous order. It is a native of India, and was introduced nearly 60 years ago to British collections. It has a twining stem of about three feet in height, and carries violet-coloured flowers. It was formerly included in the genus Dolichos, but it now constitutes a genus of itself, and takes the specific name of hispid.

SOLANDRA. A genus of tropical, ornamental, ligneous plants of the nightshade order. Two climbing species of between 15 and 25 feet in height, and three evergreen shrubs of from 3 to 14 feet in height, have been introduced to the hothouse collections of Britain; and they love a rich soil, and are propagated from cuttings.

SOLANIA. A vegetable alkali, found in the woody nightshade, *Solanum dulcamara*, and in other plants of the solanum genus. It occurs in combination with malic acid, and is precipitated from the expressed and filtered juice of the ripe berries by means of ammonia. It is naturally impure and of a grey colour; but may readily be purified by solution in hot alcohol,—and is left by the slow evaporation of the solution in the form of a white pearly powder. It is insoluble in cold water, and soluble only in at least 8,000 times its weight of hot water. It has a bitter taste, and forms neutral salts by combination with acids.

SOLANUM. See Nightshade.

SOLDANELLA. A genus of low-growing, hardy, ornamental, evergreen, herbaceous plants, of the primrose family. Eight or nine species and well-marked varieties have been introduced to Britain from Switzerland and Germany, and are fine spring-blooming beauties of the open flower border. They have a height of only from two to six or seven inches, and for the most part carry either blue or purple flowers, and are propagated by division of the roots. The oldest known species, the alpine, *Soldanella alpina*, introduced from Switzerland about the middle of the 17th century, may be taken as a specimen of the whole. Its root is fibrous; its leaves stand on long footstalks, and are almost kidney-shaped, and have a dark green colour, and measure about three-fourths of an inch over each way; its floral footstalk rises from among the leaves, and is naked, and has a height of about 4 inches; its flowers are two in number, and appear at the top of the footstalk, and are small, open, and bell-shaped, with the rim cut into many fine segments like a fringe, and have commonly a blue or purple colour, but sometimes a snow-white one, and bloom in April; and its capsule is oval, and contains very small acute-pointed seeds, and ripens in July. It requires a shaded situation.

SOLDER. An alloy for cementing together two surfaces or edges of metal. Fine solder used by tinsmiths, and much employed for tinning copper, consists of two parts of tin and one of lead, and fuses at about 360° Fahrenheit; coarse solder, used by glaziers, contains one-fourth of tin, and fuses at about 500° Fahrenheit; and hard solder, used by braziers, and requiring the copper at the time of application to be heated to near its point of fusion, is a mixture of zinc and brass.

SOLE. See Plough and Foot.

SOLEA. An ornamental, hardy, perennial-rooted herbaceous plant, of the violet family. It is a native of North America, and was introduced about 60 years ago to Britain. It has a height of about a foot, and carries herbaceous-coloured flowers in June and July. It was formerly ranked as a true violet; but it now constitutes a genus of itself, and is specifically called the self-coloured.

SOLIDAGO. See Golden-Rod.

SOLLYA. A genus of ornamental, exotic plants, of the pittosporum family. The various-leaved and the narrow-leaved species, both evergreen, blue-flowered, summer-blooming twiners, of between 4 and 10 feet in height, were introduced to Britain in 1823 and 1830 from Australia; and they require greenhouse treatment, and love a soil of peaty loam, and are propagated from cuttings. Several other species have subsequently been introduced.

SOLOMON'S SEAL,—botanically *Polygonatum*. A genus of ornamental, perennial-rooted, herbaceous plants, of the smilax order. The common or angular or many-kneed species, *Polygonatum vulgare*, called by the old botanists *Convallaria polygonatum*, is a native of the rocky mountainous woods of some parts of England, and often has a place in gardens. Its root is creeping and fleshy; its stems are angular and from 12 to 30 inches high; its leaves are alternate, clasping, broadly elliptical, acute, ribbed, and plaited; its flowers come out on axillary drooping footstalks, and are generally solitary but sometimes binary, and are pendulous and conical, and have white and green colours, and emit a powerful odour similar to that of hawthorn or heliotrope, and bloom in May and June; and its fruit are dark blue berries, of a spherical form, about the size of those of ivy, each enclosing three seeds. The roots abound in a starchy jelly, and yield starch by grating and washing, and are said to have been used in the north of Europe for making bread. A variety with double flowers and a very sweet odour occurs in gardens.—The many-flowered species, *Polygonatum multiflorum*, called by the old botanists *Convallaria multiflora*, is a native of the woods and thickets of various parts of Britain. Its stem is smooth, cylindrical, and about 2 or 2½ feet high; its leaves have a lighter green colour than those of the common species; and its flowers number

from two to five on each stalk, and are more cylindrical and elongated than those of the common species, and have a white colour and a very faint odour, and bloom in May and June.—The whorl-leaved species, *Polygonatum verticillatum*, called by the old botanists *Convallaria verticillata*, is a native of the woods of some parts of Scotland, but is very rare. Its stem is 12 or 15 inches high; and its flowers are white.—Nine or ten species have been introduced from Nepaul, Caucasus, Continental Europe, and North America; and all are white-flowered, and love a soil of sandy loam; and, in common with the indigenous species, are most readily propagated by division of the root.

SOLORINA. A genus of lichens, of the idiothalamous tribe. The yellow species, *S. crocea*, is of some economical use as a dye-stuff. It occurs on the tops of mountains in some parts of Britain, and has an olive-green colour, and a height of about 1½ inch. The hollowed species, *S. saccata*, inhabits earthy spots in Britain, and has a greyish colour, and a height of about 2 inches. Both these species have the form of leafy fronds.

SONCHUS. See Sow-Thistle.

SOOT. Condensed or embodied smoke. It is clammy and earthy, and possesses a certain degree of volatility; yet, though all originally smoke, it cannot be re-expanded into that state. It condenses on the sides of chimneys, and has escaped perfect combustion in consequence of insufficient contact with oxygen. It owes its blackish and brownish colours to the presence of carbonaceous matter in a condition similar to that of smotheredly burnt oil. It affords by distillation ammoniacal salts and empyreumatic oil, and yields to hot water a brown extract of a bitter taste; and when burnt in an open fire, it flames with a thick smoke, and produces other soot, which is used in making sal ammoniac. A specimen of soot taken from a chimney where wood had been the fuel was found by M. Braconnot to contain 30 per cent. of ulmic acid, 20 of azotic matter soluble in water, 3·9 of insoluble carbonated matter, 1 of silica, 14·7 of carbonate of lime, a trace of carbonate of magnesia, 0·5 of sulphate of lime, 1·5 of ferruginous phosphate of lime, 0·4 of chloride of potassium, 4·1 of acetate of potash, 5·7 of acetate of lime, 0·5 of acetate of magnesia, a trace of acetate of iron, 0·2 of acetate of ammonia, 0·5 of an acrid and bitter principle, and 12·5 of water. But soot greatly varies in composition, according to the nature of the substances from whose combustion it is obtained, and according to the dimensions of the chimney and the intensity of the heat. Soot from the combustion of coals is usually reckoned better for manure than that from the combustion of wood or peat; and soot from kitchen chimneys impregnated with the effluvia of cooked victuals, better than that from the chimneys of a parlour or a furnace; and soot from any chimneys of ordinary dwelling-house heat and draught, very much better than from chimneys whose heat and draught are great. Its most active manurial principle in any case seems to be its ammonia; and this is commonly exhausted in a single season, and sometimes acts so energetically as to deteriorate the succeeding crops. Its fertilizing action is more favourable to potatoes than to turnips, and more to the cereal and the pasture grasses than to clover or any other leguminous crops.

Soot mixed into water, in the proportion of about six quarts to a hogshead, has been found an excellent liquid manure for the purposes of the garden. "Asparagus, pease, and a variety of other vegetables," says Mr. John Robertson, "I have manured with it with as much effect as if I had used solid dung. But to plants in pots, particularly pines, I have found it admirably well adapted. When watered with it, they assume a deep healthy green, and grow strong and luxuriant. I generally use it and clean water alternately, and always overhead in summer; but except for the purpose of cleansing, it might be used constantly with advantage." It probably might also have the advantage of keeping pines pretty clear of scale and bugs.

A compost of soot and soil and farm-yard manure forms a sort of soapy earth, and serves as a good top-dressing to meadows, and acts beneficially on almost all kinds of plants. The mixture should be formed of two parts of earth, one part of soot, and one part of dung. A layer of earth should be covered with soot, over which a layer of dung should be placed, and thus alternate layers must be arranged in a bed about three or four feet high, and three wide. Soot, mixed with the earth dug from the ditches in the proportion of one-fourth, may, in about six months afterwards, be used with success in dressing meadows. Of this latter mixture about thirty bushels should be used to the acre. Spread on wet grounds, it will destroy the moss, and neutralize the bad qualities of the soil. When soot is applied in its simple state, it is found to answer best on light gravel, limestone, or chalk soils; but, in a state of compost, it is equally useful and applicable to almost any soil, provided the compost be such as to maintain its powers in their integrity. "The most approved mixture," says Sir John Sinclair, "is one part soot, five parts earth, one part lime. The earth and soot should be well mixed, and remain ten days at rest, then be turned, and the lime added in regular strata, as it is turned over. In this state it may continue for five or six weeks, when it ought to be turned a second time, breaking every piece as small as possible, by working it well with the spade. In a week or two more, it will be ready for use." But Sir John, notwithstanding his distinguished eminence as an agriculturist, was no agricultural chemist, and has here fallen into a gross error, and recommended a very bad practice under the description of "most approved;" for the mixing of lime with soot withdraws the latter's ammonia, and

in consequence denudes it of its chief principle of value.

Soot, either in its simple state or in mixture with water, has long been used by many farmers as a top-dressing on culmiferous crops and on grass lands, and also on turnips soon after brairding as a preventive of the fly. "On wheats that look sickly or infested with the grub worms," says Mr. Donaldson, "soot will work a great change in restoring the green healthy colour, and in causing much tillering from the roots. On clovers, tares, and on all young grasses and grass lands, the effects will be equally beneficial; and also on young barley and on all spring crops. It may also be harrowed in with the seeds of any crops in the spring on well pulverized lands; but as moisture is necessary for its operation, it may sooner derive the assistance of that element by lying on the surface as a top-dressing." "In 1838," says Mr. Main, "I applied soot to a field of wheat which, at the time, seemed in so very precarious a state as to make me even despair of its recovery. After applying the soot, however, it rallied; and when cut down, there was not a better crop on the farm. I also tried the effects of soot on a small piece of pasture, upon which a few sheep were afterwards put to graze. The result was curious. There were many other ridges in the field besides those dressed with soot, and all good grass; but the sheep continued to eat the sooted ridges until they were completely bared. With faces quite blackened they fed heartily on the soot-dressed pasture." Cattle also have been observed to prefer the grass grown on lands dressed with soot; and extensive pastures in some districts where the practice has been followed of giving them copious top-dressings of soot every year, have acquired a sort of celebrity for the vivid green of their verdure. The best time of application, in the case of almost all the crops and lands which derive most benefit from soot, is March or April; the kind of weather always desirable at the time of application, and which ought to be waited and watched for, is mild, calmly windy, and moist or showery; and the quantity proper for manurial top-dressing, varies from 20 to 100 bushels per acre, and averages between 40 and 60,—and for prevention of the fly on young turnip-crops, is about 20. Soot in its simple state has also been used in the garden, both dug into the soil and in the way of top-dressing, as a preventive of the worm in carrots and other culinary plants; but whenever it is the best thing which a gardener or cottier can obtain for any horticultural purpose, it ought to be applied in mixture with water in the way of liquid manure.

The common mode of applying simple soot as a top-dressing in the field is by hand-sowing. The waggon or cart containing it should be driven across the wind; and the sowing should be so done that the soot may be gently carried away by the wind from the horses and the sower. But a soot-distributing machine was invented a few years ago by Mr. Main, and is described and figured in the 12th volume of the Highland Society's Transactions, and may be well worth the attention of any farmer who purposes to make extensive use of soot. It comprises a chest mounted on two wheels, from which motion is communicated to a sheet-iron cylindrical riddle, in which the soot is placed. The soot is separated by the riddle from the stones and mortar which are generally mixed with it; and it falls thence to the bottom of the chest, and falls through orifices of this to the ground in a very similar way to that in which the seeds fall from a broadcast-sowing machine. —*Davy's Agricultural Chemistry by Shier.—Donaldson on Manures.—Repertory of Inventions.—General Report of Scotland.—Loudon's Gardener's Magazine.—Transactions of the Highland Society. — Q. Journal of Agriculture. — Boussingault's Rural Economy.—Bayldon on Rents and Tillages.*

SOPHORA. A genus of ornamental exotic plants, constituting the type of a large tribe of phyllolobous leguminosæ. See the article Leguminous Plants. The Japanese species, *S. japonica*, is a deciduous timber-tree of Japan, and was introduced to Britain, according to various statements, in 1780, in 1763, or in 1753. It has been cultivated in France since 1717; and it is quite hardy in Britain, and occupies a somewhat prominent place in good collections of small ornamental trees. It attains a height of upwards of 20 feet; with a proportionate diameter. Its wood, when fresh cut, emits an odour offensive to insects; its leaves are pinnated and smooth, and have a beautiful green colour, and give to the tree a graceful appearance; its flowers are white, and bloom in August and September; and its pods are long, slender, one-celled, and numerous, and have prominent knobs on the surface. It is propagated from seeds, sown as soon as they can be procured in pots filled with light earth; and its plantlets should be planted in a sandy loam, and in a sheltered situation. One variety of it is pendulous, and another has variegated leaves.—The Chinese species, *S. sinensis*, was introduced to Britain from China in 1818; and is also a hardy, deciduous, white-flowered, small tree, scarcely so tall as the Japanese. — Four hardy, perennial-rooted, herbaceous species, of from 1½ to 4 feet in height, and chiefly yellow-flowered, have been introduced from Siberia, North America, and the Levant; and a number of tropical, evergreen, ligneous species, varying in height from 3 to 20 feet, and carrying variously white, yellow, violet, or purple flowers, have been introduced from India and tropical America.

SOPHRONITIS. A genus of ornamental, tropical, epiphytous plants, of the orchis order. It is nearly allied to the splendid genus cattleya. The drooping species, *S. cornua*, was introduced to Britain from Rio Janeiro in 1827,—and the large-flowered species, *S. grandiflora*, from the

Organ mountains in 1837; and the former is 3 or 4 inches high, and has red flowers,—the latter 6 or 8 inches high, and has scarlet flowers.

SORBUS. See PYRUS and ASH (MOUNTAIN).

SORGHUM. See INDIAN MILLET.

SOROCEPHALUS. A genus of ornamental, evergreen, purple-flowered, Cape-of-Good-Hope shrubs, of the protea family. Seven or eight species, varying in height from 2 to 4 feet, and chiefly blooming from about midsummer till the early part of autumn, have been introduced to the gardens of Britain; and most love a soil of loamy peat, and are propagable from cuttings.

SORREL. Three hardy, culinary, perennial-rooted herbaceous plants, of the dock genus. Two of them, the common sorrel and the sheep's sorrel, are natives of Britain; and the other, French sorrel, was introduced about 250 years ago from France.

Common sorrel, *Rumex acetosa*, is the best known and naturally most abundant of the three species. Its root is long, tapering, and somewhat woody, and has astringent properties; its stem is cylindrical, striated, erect, simple, leafy, and from 12 to 24 inches high; its leaves are oblong, ovate, and arrow-shaped,—smooth in texture, and powerfully and agreeably acidulous,—the radical ones stalked and obtuse,—and the cauline ones sessile, clasping, pointed, and a little rolled back; and its flowers are dicœcious, and grow in branched panicles, arranged in half-whorls, and have permanent tuberculated petals of a greenish colour, and bloom in June and July. The astringency of the root is due to tannic acid; and the acidulousness of the leaves to tartaric acid and the binoxalate of potash.

Sorrel inhabits the wild grassy pastures of most parts of Continental Europe, from Greece to Lapland; and it is common in many of the pastures, both high and low, of Britain,—and it indicates a sour state of the soil, which cannot ordinarily be corrected without an application of calcareous manure,—and as it is never eaten by live stock, except when they are hard pressed by hunger, and cannot get better food, it has practically the character of a rank coarse weed, which both impoverishes the ground by its own growth, and keeps down useful herbage by its occupancy and its shade. It becomes specially abundant and luxuriant in seasons when the spring growth of the grasses is backward and stunted; it seems generally to abound in the proportion in which free humic acid exists in the soil; it can easily be kept down or starved out by means of liming or of the application of soap-maker's waste; and the extermination of it from some fields which it specially infests, would permanently increase their value from 30 to 50 per cent.

Sorrel has been celebrated from very ancient times for its cooling, antiscorbutic, diuretic, and gratefully esculent properties. The expressed juice of its leaves, or a decoction of them in whey, affords an useful drink in cases of inflammatory fever; and the leaves themselves, eaten freely as a salad, cool the blood and act as either a cure or a preventive of scurvy. The plant is cultivated in France and in some English gardens as a highly esteemed pot-herb, and for use at all seasons in soups, sauces, and salads; it is far worthier of a large and constant place in the kitchen garden than many of the plants which commonly figure there; and it seems to be hindered only by the caprice of fashion from being a general and useful favourite. It is even employed in some parts of northern Europe, in seasons of scarcity, as one of several substitutes for bread. It thrives best in any garden mould which is moderately rich and more friable than tenacious; and it may be raised either from seeds sown in spring, and the seedlings transplanted, or from offsets and divisions of the root in either spring or autumn, planted at distances of a foot.

The sheep's sorrel, *Rumex acetosella*, is a common and plentiful weed of dry banks and gravelly soils in most parts of Britain; and, whenever it gets possession of any spot of ground, it propagates itself promptly and rapidly by means of its spreading roots, and soon becomes abundant. Its stem is wavy, slender, often decumbent, and generally about a foot long; its leaves, in the lower part of the stem, are hastate,—and in the upper part, lanceolate-hastate; and its flowers are dicœcious, small, and separate, and grow in numerous, whorled, leafless clusters, and bloom from May till July. This plant has similar taste and properties to the common dock, and was formerly noticed in the dispensatories as a medicinal plant; but it is inferior to the common dock, and is not so much used.

The French or Roman or bucklered sorrel, *Rumex scutatus*, closely resembles the common sorrel in properties and uses, but has a different habit of growth, and loves a light, dry, rich soil in an open situation, and is preferred by some persons on account of the facilities of its cultivation, and by others for the sake of its superior adaptation to soups. "It is," says Miller, "a great runner at the root, by which means it is easily propagated, and must be planted at a large distance, two feet square at least. And if the flower-stems and rambling branches are cut off in the beginning of July, the roots will soon put out new leaves; so that by cutting down the shoots of some plants at different times, there will always be a supply of young leaves, which is the only part of the plant used in the kitchen."

SORREL (MOUNTAIN). See MOUNTAIN SORREL.

SHEEP SORREL. See SORREL.

SORREL TREE. A hardy, evergreen, ornamental, North American tree, of the andromeda genus, and heath order,—*Andromeda arborea*. It was introduced to Britain about the middle of last century. It commonly attains a height of about 40 feet; and it carries white flowers from

July till September. It loves a soil of sandy peat, and is propagated from seed.

SORREL (Wood). See Wood Sorrel.

SOUNDNESS. Freedom from injury or defect,—or, in the case of a horse, the absence of everything which impairs now, or may probably impair hereafter, his natural usefulness. The constituents of soundness in horses are ill defined, both in the phraseology of common life and in that of the law; and they afford occasion for a perfect wilderness of disputes in the horse-market, and render it quite unsafe for an inexperienced person to purchase a horse without the aid of a professional man, or without a full written warranty of soundness from the seller. Youatt pronounces unsoundness to have "reference only to disease, or to that alteration of structure which is connected with or will produce disease, and lessen the usefulness of the animal;" and he enumerates, as "the usually supposed appearances or causes of it," broken knees, capped hocks, contraction, corns, cough, roaring, wheezing, whistling, high-blowing and grunting, cribbiting, curb, cutting, enlarged glands, enlarged hock, inflammatoriness of the eyes, lameness, neurotomized leg, ossification of the lateral cartilages, pumiced foot, quidding, quittor, ringbone, sandcrack, spavin, bog-spavin, splint, string-halt, thickening of the back sinews, thoroughpin, thrush, and windgalls. See the article Warranty.

SOUR GOURD. See Adansonia.

SOUR GUM. See Nyssa.

SOURCIC ACID. See Apocrenic Acid.

SOUR LAND. Land which contains free humic acid, and requires an application of calcareous manure for the promotion of its fertility. See the articles Soil and Lime.

SOUTHERNWOOD. Several species of hardy ornamental plants, of the wormwood genus.—The field species, *Artemisia campestris*, grows wild in the sandy fields of some parts of England, but is rare. It is a perennial-rooted herb, and possesses little resemblance to the ordinary southernwoods of gardens, and has no aromatic or bitter flavour. Its stems are straight, wand-like, leafy, smooth, often reddish, and commonly from 12 to 24 inches long, and at first are prostrate, but afterwards become more or less upright as the flowers appear; its leaves are irregularly and doubly pinnatifid, and have blunt and in many instances linear leaflets; and its flowers are ovate, small, and drooping, and have a yellow colour with a purplish calyx, and form numerous slender leafy clusters at the ends of the stems and the branches, and bloom in August. A variety called the alpine, *A. c. alpina*, was introduced about 30 years ago from Switzerland.—The most common southernwood of gardens, *Artemisia abrotanum*, is a native of the south of Europe, and was introduced to Britain about the middle of the 16th century, and has long been one of the most favourite ornamental plants of cottage flower-plots, and is everywhere known and liked for the agreeable aromatic odour of its herbage. It is a hardy deciduous shrub, of commonly about 4 feet in height. Its stems are simple; its leaves are bipinnatifid and smoothish; and its flowers have a herbaceous colour, and bloom from August till October. It thrives in any common garden soil, and is easily propagated from cuttings. —The other garden southernwoods have a general resemblance to the abrotanum; yet, in some instances, are quite as like the mugworts and the true wormwoods; and they greatly vary in odour, in hoariness, in foliage, and in other characters. See the articles Mugwort and Wormwood.

SOW. See Hog.

SOWBREAD. See Cyclamen.

SOWENS. See Oat.

SOWERBÆA. An ornamental, greenhouse, pink-flowered, evergreen, herbaceous plant, of the asphodel family. It is a native of Australia, and was introduced about 56 years ago to Britain. It has commonly a height of about a foot; and blooms from May till July. It constitutes a genus of itself; and is specifically called *juncea*, or "the rush-leaved."

SOWING. The depositing of seed in the soil. The several methods of it are comprised in broadcasting, drilling, and dibbling, and are described in the articles Broadcast-Sowing, Drill-Husbandry, and Dibbling. The comparative advantages of the broadcasting and the drilling methods are also noticed in the article Drill-Husbandry. Points preliminary to sowing, and having reference to the seed, are discussed in the article Seed; points preliminary to sowing, and having reference to the state of the soil, are discussed in the article Ploughing; some points which have reference to the economy of sowing are noticed in the article Agricultural Seeds; points which have reference to the season and meteorological circumstances of sowing are noticed in the articles on all the principal field and garden crops; subjects connected with the implements specially employed in sowing are noticed in the articles Sowing Machines and Implements; and points which have reference to the immediate chemical and physiological results of sowing are discussed in the article Germination.

The comparative advantageousness of thick and of thin sowing is complicated with the comparative advantageousness of the broadcasting and the drilling methods, with the specialities or modifications in the practice of each, with the nature, condition, and tilth of the soil, with the season, weather, and other circumstances of sowing, and with the species and varieties of the crops sown; so that both arguments from theory and appeals to experiment may very readily be conducted with such incautiousness or such incomprehensiveness as to bring out apparently triumphant conclusions on either side of the

question. Most of the reports of experiments which have been published, and which have given rise to much keen discussion, whether those which favour thin sowing or those which favour thick sowing, throw little or no real light on the general question, and are useful principally in pointing out certain combinations of circumstances in which respectively thin sowing and thick sowing have been found most advantageous. One of the most judicious of the experimenters who brings out results in favour of thin sowing, and who tried both barley and wheat in different quantities in the drill method, is candid and comprehensive enough to say, "Thin sowing should be early sowing on heavy land. It would be a dangerous experiment to sow thinly unless the land were drained, subsoiled, and kept free from weeds by the horse-hoe. Some allowance should be made for game near preserves. On reclaimed bog, or deep rich vegetable soil, I find it imperative to sow thin, or the crop would be mostly straw. Thin sowing somewhat delays the ripening of a crop, especially of wheat sown on heavy land so late as November or December. In cold or elevated districts, thin sowing, to succeed, must be very early. In my experiments, anything beyond one bushel of wheat seed per acre has not had the effect of increasing the yield, the extra seed being lost. It is a singular fact that the one bushel per acre never changed yellow in the spring, but went on with a healthy green cast without a check; the two bushels turned yellow, and the three bushels yellower, and was decidedly the worst stetch in the field. I would venture to suggest that each farmer should satisfy his own mind by trying part of an acre on each field. We seldom hear complaints of the losses from thick sowing in rich soil; they are, however, very serious in moist luxuriant summers. Two friends of mine sowed 4 bushels per acre, and only got 4 quarters of grinding barley, which sold at 27s. 6d., — they had an abundance of crowded weakly straw, which was laid early; mine, dibbled at 3 pecks per acre in not near so good a soil, produced 6 quarters, which sold for 33s. 6d., with strong straws and ears containing 17 to 19 kernels on each side." A writer on the opposite side of the question, and who at first seems almost red hot against thin sowing, also makes concessions and modifications which show that the whole question is one of an aggregate of circumstances, and ought to be decided by each farmer for himself according to soil, crop, season, and culture. "No harm," remarks this writer, "can eventually result from testing the thin-sowing plan of farming, although I expect many a poor farmer will be induced to try it, and pay for the trial by the loss of half of one year's crop. We all know that, if the land be sown with too much seed, the crop is injured— and if carried to a great extent, would be entirely lost,—the truth of which every one can testify from his own observation. On the other hand, too little seed will have the effect of depriving the farmer of a full crop. The question then is, what is a fair amount of seed to sow? I take it that that entirely depends upon the quality and situation of the land. If a person were to sow two pecks of wheat to the acre upon the Surrey hills, he would have room enough at harvest to drive a coach and four between the plants, because although it seems a paradox to say that the poorest land requires the most seed, it certainly is so, and for the following reasons: —first, because the land being cold and poor, and perhaps stiff, a very great proportion of the seed will not vegetate at all; and secondly, because upon poor land the plants do not tiller as they do upon good land. The only justification for sowing a small quantity of seed upon poor land would be drilling it in; but this operation could not well be performed upon the flinty hills of Surrey; and if it could, the seed should be deposited very close, for the reason given above, namely,—because the plants do not tiller or branch out,—also because horse-hoeing, so necessary when the crop stands thin upon the ground, cannot be performed satisfactorily, if at all, upon ground which contains so many flints as the Surrey hills do. It is another thing upon good rich fertile land, where every grain deposited will vegetate, and which, when up, will, in the spring tiller and increase its number of plants, and not only so, but will bring them all to perfection. The land also, being kind, can be horse-hoed, and nourishment added by the operation."

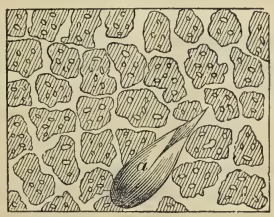
Two main things which claim attention in connexion with sowing — things on which the economising of the seed, the success and vigour of germination, and the regularity, strength, and luxuriance of the crop, very largely depend—are the proper mechanical condition of the soil, and the proper and uniform depth at which the seed is deposited; and these are so admirably stated in a lecture of Dr. Madden, which was read to a meeting of agriculturists at the great annual show of the Highland Society in Edinburgh, in August 1842, and afterwards published in the 14th volume of the Society's Transactions, that we cannot do better than present an abstract of that lecture to our readers:—

"The most careful examination has proved, that the process of germination consists essentially of various chemical changes, which require for their development the presence of air, moisture, and a certain degree of warmth. Now, it is obviously unnecessary for our present purpose, that we should have the least idea of the nature of these processes: all we require to do, is to ascertain the conditions under which they take place; having detected these, we know at once what is required to make a seed grow. Viewing matters in this light, it appears that soil does not act chemically in the process of germination,—that its sole action is confined to

its being the vehicle by means of which a supply of air, and moisture, and warmth, can be continually kept up. With this simple statement in view, we are quite prepared to consider the various conditions of soil, for the purpose of determining how far these will influence the future prospects of the crop; and we shall, accordingly, at once proceed to examine carefully into the mechanical relations of soil. This we purpose doing by the aid of figures.

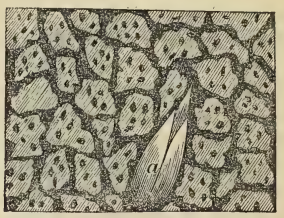
"Soil, examined mechanically, is found to consist entirely of particles of all shapes and sizes, from stones and pebbles down to the finest possible powder; and, on account of their extreme irregularity of shape, they cannot lie so close to one another as to prevent there being passages between them, owing to which circumstance, soil in the mass is always more or less porous. If, however, we proceed to examine one of the smallest particles of which soil is made up, we shall find that even this is not always solid, but is much more frequently porous, like soil in the mass. A considerable proportion of this finely divided part of soil, the impalpable matter as it is generally called, is found, by the aid of the microscope, to consist of broken down vegetable tissue; so that when a small portion of the finest dust from a garden or field is placed under the microscope, we have exhibited to us particles of every variety of shape and structure, of which a certain part is evidently of vegetable origin. In these figures I have given a very rude representation of these particles; and I must beg you particularly to remember that they are not meant to represent, by any means accurately, what the microscope exhibits, but are only designed to serve as a plan by which to illustrate the mechanical properties of the soil.—On referring to *fig.* 1, we perceive that there are

Fig. 1.



two distinct classes of pores,—1st, the large ones, which exist between the particles of soil, and, 2d, the very minute ones, which occur in the particles themselves; and you will at the same time notice, that whereas all the larger pores, those between the particles of soil, communicate most freely with each other, so that they form canals, the small pores, however freely they may communicate with one another in the interior of the particle in which they occur, have no direct connexion with the pores of the surrounding particles. Let us now, therefore, trace the effect of this arrangement. In *fig.* 1, we perceive that these canals and pores are all empty; the soil being perfectly dry, and the canals communicating freely at the surface with the surrounding atmosphere, the whole will of course be filled with air. If, in this condition, a seed be placed in the soil, as at *a*, you at once perceive that it is freely supplied with air, but there is no moisture; therefore, when soil is perfectly dry, a seed cannot grow.—Let us turn our attention now to *fig.* 2. Here we perceive that both the pores and canals are no longer represented white but

Fig. 2.



black, this colour being used to indicate water. In this instance, therefore, water has taken the place of air, or in other words, the soil is very wet. If we observe our seed *a* now, we find it abundantly supplied with water, but no air. Here again, therefore, germination cannot take place. It may be well to state here, that this can never occur exactly in nature, because water, having the power of dissolving air to a certain extent, the seed *a* in *fig.* 2 is in fact supplied with a certain amount of this necessary substance; and, owing to this, germination does take place, although by no means under such advantageous circumstances as it would were the soil in a better condition.—We pass on now to *fig.* 3. Here we find a different state of matters. The canals are open and freely supplied

Fig. 3.

with air, while the pores are filled with water; and consequently you perceive that, while the seed *a* has quite enough of air from the canals, it can never be without moisture, as every particle of soil which touches it is well supplied with this necessary ingredient. This, then, is the proper condition of soil for germination, and in fact for every period of the plant's development; and this condition occurs when soil is moist, but not wet; that is to say, when it has the colour and appearance of being well watered, but when it is still capable of being crumbled to pieces by the hands, without any of

its particles adhering together in the familiar form of mud.—Turning our eyes to *fig.* 4, we

Fig. 4.

observe still another condition of soil; in this instance, as far as water is concerned, the soil is in its healthy condition—it is moist, but not wet—the pores alone being filled with water. But where are the canals? We see them in a few places, but in by far the greater part of the soil none are to be perceived; this is owing to the particles of soil having adhered together, and thus so far obliterated the interstitial canals that they appear only like pores. This is the state of matters in every clod of earth *b*; and you will at once perceive, on comparing it with *c*, which represents a stone, that these two differ only in possessing a few pores; which latter, while they may form a reservoir for moisture, can never act as vehicles for the food of plants, as the roots are not capable of extending their fibres into the interior of a clod, but are at all times confined to the interstitial canals.

"With these four conditions before us, let us endeavour to apply them practically, to ascertain when they occur in our fields, and how those which are injurious may be obviated. The first of them, we perceive, is a state of too great dryness, a very rare condition, in this climate at least; in fact, the only case in which it is likely to occur is in very coarse sands, where the soil, being chiefly made up of pure sand and particles of flinty matter, contains comparatively much fewer pores; and, from the larger size of the individual particles, assisted by their irregularity, the canals are wider, the circulation of air freer, and consequently the whole is much more easily dried. When this state of matters exists, the best treatment is to leave all the stones which occur on the surface of the field, as they act as shades, and thereby prevent or retard the evaporation of the water. We will not, however, make any further observations on this very rare case, but will rather proceed to *fig.* 2, a much more frequent, and, in every respect, more important condition of soil,—I refer to an excess of water. When water is added to perfectly dry soil, it of course, in the first instance, fills the interstitial canals, and from these enters the pores of each particle; and, if the supply of water be not too great, the canals speedily become empty, so that the whole of the fluid is taken up by the pores; this, we have already seen, is the healthy condition of soil. If, however, the supply of water be too great, as is the case when a spring gains admission into the soil, or when the sinking of the fluid through the canals to a sufficient depth below the surface is prevented, it is clear that these also must get filled with water so soon as the pores have become saturated. This, then, is the condition of undrained soil. Not only are the pores filled, but the interstitial canals are likewise full, and the consequence is, that the whole process of the germination and growth of vegetables is materially interfered with. Of course all the injurious effects are at once overcome by thorough-draining, the result of which is to establish a direct communication between the interstitial canals and the drains, by which means it follows, that no water can remain any length of time in these canals without, by its gravitation, finding its way into the drains.—The fourth figure indicates badly cultivated soil, or soil in which large unbroken clods exist. Too much cannot be said in favour of pulverizing the soil; even thorough-draining itself will not supersede the necessity of performing this most necessary operation. The whole valuable effects of ploughing, harrowing, grubbing, &c., may be reduced to this; and almost the whole superiority of garden over field produce is referable to the greater perfection to which this pulverizing of the soil can be carried. The whole success of the drill husbandry is owing, in a great measure, to its enabling you to stir up the soil well during the progress of your crop; which stirring up is of no value beyond its effect in more minutely pulverizing the soil, and increasing, as far as possible, the size and number of the interstitial canals. Lest any one should suppose that the contents of these interstitial canals must be so minute that their whole amount can be of but little consequence, I may here notice the fact, that in moderately well pulverized soil they amount to no less than one-fourth of the whole bulk of the soil itself. For example, 100 cubic inches of moist soil (that is, of soil in which the pores are filled with water while the canals are filled with air) contain no less than 25 cubic inches of air. According to this calculation, in a field pulverized to the depth of 8 inches, a depth perfectly attainable on most soils by careful tillage, every imperial acre will retain beneath its surface no less than 12,545,280 cubic inches of air. Taking into the calculation the weight of soil, we shall find that, with every additional inch which you reduce to powder (by ploughing, for example, 9 inches in place of 8), you call into activity 235½ tons of soil, and render it capable of retaining beneath its surface 1,568,160 additional cubic inches of air. And to take one more element into the calculation, supposing the soil were not properly drained, the sufficient pulverizing of an additional inch in depth would increase the escape of water from the surface by upwards of 100 gallons a day, a quantity

which would very soon tell upon the dryness of soil, if there were a continuance of dry weather for several successive days, more especially if this were accompanied by sunshine. From what I have now stated, I humbly hope that you cannot fail to perceive the close connection which subsists between the mechanical condition of the soil and the result of germination; and that you have at the same time felt satisfied of the degree of certainty and point which all the processes of preparing the soil assume, when the principles on which they depend are fully understood and appreciated.

"Hitherto we have spoken only of the condition of the soil at seed-time; we shall now examine into the various methods in use for sowing the seed, and determine what effect these can have upon the value of the resulting crop. It is well known to you all, that, until lately, the grain crops were almost universally sown broadcast upon the furrow-slice, which process has the effect of imitating, to a certain extent, the drill-system. A very few considerations, however, will suffice to point out, that with this system of sowing your success is so far dependent upon the skill of your workmen, that you may be considered completely at their mercy. To demonstrate this, let us refer to the figures below, which are designed to show the effects produced by bad ploughing and bad sowing, as compared with the results obtained by the use of machines. In *fig.* 5, you have an example of bad ploughing. You will at once perceive, that, in this case, the ploughman has either had a very unsteady pair of horses, or has been but little experienced in his employment. At *a*, for example, he has given his plough too much land, and has turned over a slice considerably broader than it should be, thus producing, as is shown in *fig* 6, a space in which too much seed will lodge. At *b* he has laid the slice too upright, thus producing what is technically termed a proud furrow, and which in another manner affects the sowing by allowing the seed to slip down between the two slices, and consequently become buried to far too great a depth below

Fig. 5.

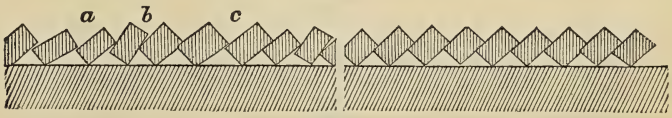


Fig. 6.

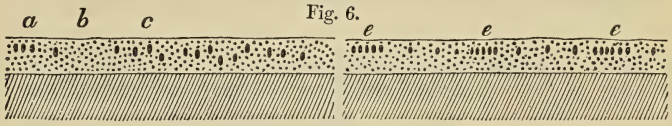

Fig. 7.

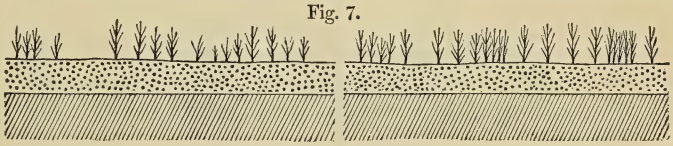
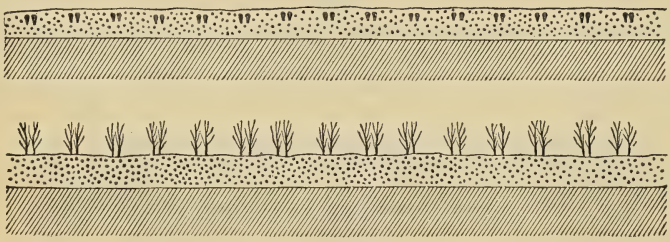


the surface. Again at *c*, by leaning the plough to the side, he has turned over a slice considerably thicker at the top than the bottom, which, in its turn, will influence the crop by stirring too little soil at certain places, and thus producing an active soil of different thicknesses. Besides these, there are various other faults in ploughing, each one of which has a distinct and visible influence on the growing of the crop. On a field thus carelessly turned over, the sower proceeds to scatter the seed; and here, again, you will at once perceive the effect which the performance of this operation will have on the resulting crop. To the left of *fig.* 6, I have supposed a good sower to be employed, but still he is labouring under the disadvantage of following a bad ploughman. The figure represents in section the position of the seeds as determined by the condition of the furrow-slice, and you will at once notice several important errors. At *a* there is too much seed; at *b* it is far too deep below the surface; at *c* it is much nearer the surface, and so forth. On the right, again, of *fig.* 6, I have endeavoured to represent the injury affected by a bad distribution of the seed, even although the ploughing has been performed in the most masterly style, as in the furrow-slices immediately above in *fig.* 5. In this case at *e* the seed is far too thick, owing to his not having opened his hand soon enough when delivering it out, and on this account the crown of the ridge is much too thinly supplied. This is a very serious, but I fear too common a fault; at least, if we carefully observe the brairding of the fields in spring, there is nothing more common than to see the furrows green, whilst the crowns of the ridges are still nearly bare.

"Let us now turn our attention to the results likely to be produced by these various errors. We have already seen that the requisites for germination are air, moisture, and a certain degree of warmth; and I may here observe, that the

temperature has a very decided influence upon the time required for germination, and that, within certain limits, the higher the temperature is the more rapidly does the process go on. But it must be kept in mind, that soil receives its heat through the medium of the air, and that, consequently, the surface is always more quickly heated than that deeper down. In fact, the heat progresses so slowly from above downwards, that it has been found that at a certain depth beneath the surface, the temperature of summer is not felt until the following winter. Whenever the air is warmer than the soil, the surface of the soil will be warmer than that below the surface; when, on the other hand, the air is cooler, the surface of the soil will, by contact, cool much more rapidly than that below the surface. From this state of matters it follows, that the most rapid germination will occur at about 1 inch or so below the surface, to which depth the heat will soon penetrate, and which, nevertheless, will not be so readily cooled during the night. On this account, the seeds at this level will generally grow most rapidly, and the germination of others will occupy more and more time, as the distance between them and the surface is increased. It is owing to this fact that seeds too deep sown do not grow at all, the temperature not being sufficiently elevated, and the supply of air too limited to set the chemical processes at work which are essential to germination. In *fig.* 7, we perceive this result very clearly demonstrated; for, while the plants at one spot, where the seeds were about 1 inch below the surface, have attained a good size, those which slipped down between the furrow-slices from the bad ploughing, have scarcely yet appeared above ground, as below *a* and *b* of *fig.* 6. Turning your attention to *fig.* 8.

Fig. 8.



you will at once perceive the immense advantage of the machine over the hand-sown crop. In this case, you can work up your land to any degree of fineness you please, by harrowing, grubbing, rolling, &c. You are preserved from every injury arising from a careless distribution of the seed; and even the errors of your ploughmen have not so serious an effect upon the result of the crop. The machine delivers the seed, as in the upper figure, with the greatest exactness, at any depth you please, and the result is, as shown in the lower figure, the greatest equality in the braird."

SOWING-MACHINES. Implements for the easy and regular distribution of seeds alone or of seeds and special manures. They did not acquire a very refined character till a comparatively recent period, and they are still unused, in even their rude state, in some of the remote and least improved districts of Britain; yet they have been known for centuries in both the extreme east and the extreme west of the civilized world, and have, for a long period, been progressively multiplied in form and kind, and anxiously studied and improved by some of the ablest agricultural mechanicians. The farmers of China, India, Japan, and Arabia have, from time immemorial, drilled and dibbled in their seeds. The Chinese sowing-machine of the present day resembles in some respects a hand-barrow and in others a small plough, and has three hollow teeth of about 28 inches in length with iron supports, and carries the seeds in a box above the wheels, and drops them thence through the teeth to the ground, in rows of from 7 to 14 inches distant; and it follows the plough, and is itself followed by a small wooden roller, which covers the seeds and supplies the place of a harrow. The Hindoos, after depositing the seed in a similar way, use a kind of subsoil plough, which loosens the soil, three drills' breadth at a time, to the depth of about 8 inches. About the middle of the 17th century, Gabriel Platte described a rude dibbling machine, which was formed of iron pins "made to play up and down like Virginal jacks;" and about twenty years later, Worlidge published an account of a seed and manure drill of his own invention, and Evelyn strongly recommended to the attention of Englishmen the sembrador drill-plough which had been invented on the Continent. See the article SEMBRADOR. At the introduction of the drill husbandry under Jethro Tull, that great improver first attempted to revive attention to the sembrador, and next invented sowing machines of his own, and endeavoured to render them fully subservient to his system. "His first invention was a drill-plough to sow wheat and turnip seed in drills three rows at a time. There were two boxes for the seed; and these, with the coulters, were placed one set behind the other, so that two sorts of seed might be sown at the same time. A harrow to cover

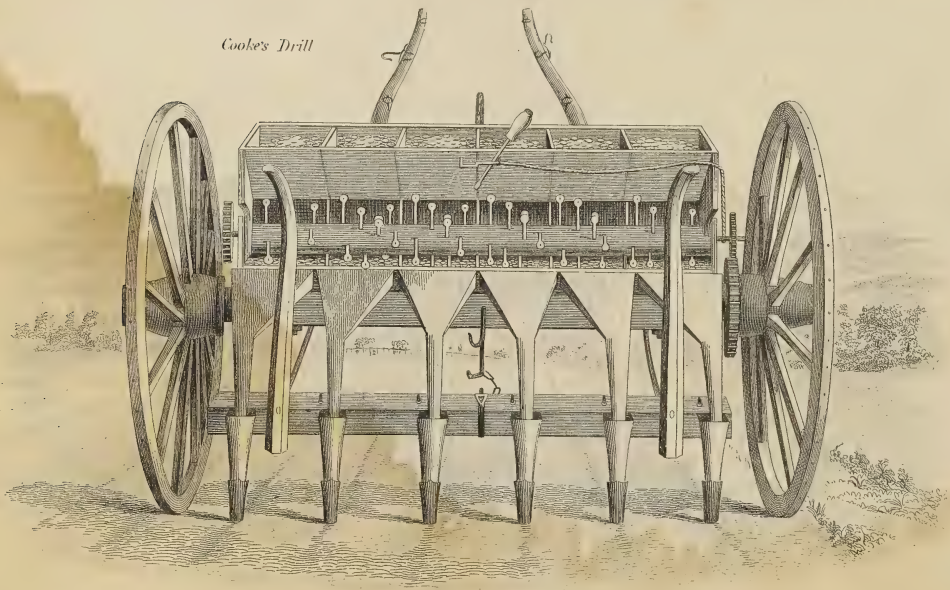
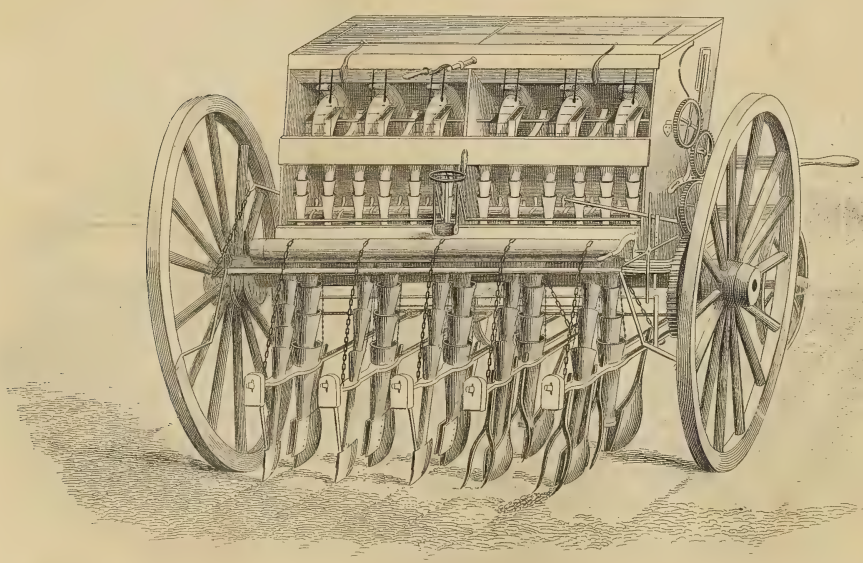
Cooke's Drill



Garrett's Drill



Engd by G.H.Swanston Edin.

in the seed was attached behind. He also invented a turnip-drill somewhat similar to the other in general arrangement, but of a lighter construction. The feeding-spout was so arranged as to carry one-half of the seed backwards after the earth had fallen into the channel; a harrow was pinned to the beam,—and by this arrangement, one-half of the seed would spring up sooner than the other, and so part of it escape the turnip-fly. When desirable to turn the machine, the harrow was to be lifted and the feeding would stop. The manner of delivering the seeds to the funnels in both the above drills was by notched barrels; and Tull was the first who used cavities in the surfaces of solid cylinders for the feeding." About the year 1776, Sir John Anstruther, near Edinburgh, invented a one-horse double drill-plough, of simple construction, for sowing two furrows at a time, with the draught-horse walking between them, so that the fine soil was not injured by the animal's feet; and, after eight years successful trial of it, he introduced it to the notice of the Bath and West of England Society. During the next ten years, ten patented machines were invented by distinguished mechanicians or agriculturists for sowing grain or for sowing and harrowing it, and two for depositing manure with the seed; and among these, in 1788, was a drilling and ploughing machine, invented by James Cooke, a clergyman of Heaton-Norris in Lancashire,—improved, two years afterwards, by Henry Baldwin, a farmer of Mendham in Norfolk,—and comprising principles of construction which have been more or less adopted in some of the best drill-machines of the most recent years. The patents taken out for drill-ploughs, sowing-machines, and improvements in drills, since the commencement of the present century, have been very numerous; and the competition in the manufacture of drill-machines among all the good and extensive agricultural implement makers of the present day, is keen and comprehensive, and brings as great a profusion and variety into the market as the most fastidious farmer could well desire.

The chief principles adopted in the construction of most drill-machines, are stated as follows by Professor Low:—"A frame-work is placed upon two wheels; and upon this is an oblong box for containing seeds. From the axle of the wheels motion is communicated to a spindle or axle, which passes horizontally through the lower part of the box; and upon this axle may be fixed, at the distances required, a series of grooved or fluted cylinders. There are apertures formed near the bottom of the box, and as each cylinder revolves amongst the seeds, a certain portion of them is collected in the grooves at each revolution, and is carried round in the grooves and falls through these apertures. By making the grooves larger or smaller, so as to contain a larger or smaller quantity of seeds, or by making the apertures of the seed-box larger or smaller, so as to allow a larger or smaller quantity of seeds to pass through, the machine can be made to sow the seeds more or less thick, as may be required. The seeds, after passing through the apertures, fall into tubes or funnels, through which they are conveyed to the ground. Immediately before the lower part of each funnel is a sharp coulter of iron, which encloses the lower part of the tube, and makes a rut in the ground into which the seeds fall. By these means they are sown in the quantity required and at the depth to which we choose to set the coulters. To allow the rows to be at larger or smaller intervals, the cylinders are generally moveable upon the spindle, so as that they may be set at any distance required, as 9, 10, 12, or more inches. The coulters are made to move at the depth required, and to be lifted up along with the tubes or funnels when necessary, as at the turning at the end of the ridges, the encountering of obstacles, and the like. Sometimes the axle, instead of having cylinders upon it with grooves, has a series of small pinions or teeth. Or, in place of the teeth, there is employed a series of stiff brushes. The teeth or brushes revolve in the same manner as the fluted cylinders, and, by keeping the seeds in motion, cause them to fall through the little apertures or holes near the bottom of the box. The holes are made to be enlarged or diminished by means of a sliding iron plate, placed upon them with an equal number of similar holes with those of the iron-plate. When the holes of the seed-box and the iron-plate correspond, that is, when they are placed exactly one upon the other, the holes through which the seeds drop are of their largest size. But by moving the iron-plate a little to a side the holes do not entirely correspond, and hence the holes through which the seeds fall are lessened; and by moving the iron-plate still further to one side, so as that no part of the two sets of holes shall correspond, those of the seed-box are entirely covered. The iron-plate which thus lessens or closes the apertures of the seed-box, is moved by a lever, and fixed in its position by screws."

Cooke's drill, in consequence of being the sort of type of most of the good modern drills, deserves particular notice, and is figured in *Plate LVII.* "The seed-box is of a peculiar shape, the hinder part extending lower than the fore part. It is divided by partitions, and supported by adjustable bearings so as to preserve a regular delivery of the seed whilst the machine is passing over uneven ground. The feeding cylinder is made to revolve by a toothed-wheel, which is fixed on each end of the main axle, and gears with other toothed wheels on each end of the cylinder; the surface of the cylinder is furnished with a series of cups which revolve with it, and are of various sizes, according to the different seeds intended to be sown. These deposit the seed regularly in funnels, the lower ends of which lead immediately behind the coulters, which are

connected by a beam, so as to be kept in an even line, and are capable of being held out of working when desired by a hook and link in the centre. The seed, as it is deposited, is covered in by a harrow fixed behind. The carriage wheels are larger in size than usual, by which means the machine is more easily drawn over uneven ground; and the labour of working is reduced." The improvements made on this implement by Mr Baldwin of Mendham consisted, "first, in making a sliding axle-tree, by which the carriage wheel could be extended at pleasure to the width of the 'stetches' or lands, and by which means another box with cups and more coulters could be used,—thus a drill containing fourteen coulters could be enlarged to one of eighteen or twenty; second, in making self-regulating levers, to which the coulters were attached,—this was done by hanging each coulter on a distinct lever, placed at right angles with the cross-bar of the framing, upon which each lever was made to swing by an ordinary hinge joint, and had a moveable weight at its opposite end, to press the coulter into the soil. By the levers being thus contrived to work independently of each other, they accommodated themselves to the irregularity of the surface of the land, and the impediments they might meet with, without disturbing the whole. These were two very important improvements; and they are both in use to this day."

The Suffolk drill is a highly improved modification of Cooke's, together with additional apparatus and more extensive adaptations; and it comprises many subvarieties, and is familiar, in some one or more of these, to a large proportion of all the better class of English agriculturists. The forms of it which are based on the improvements of the Messrs. Smyth of Peasenhall and Swefling—two brothers who followed in the tract of Mr. Baldwin of Mendham, and continued to pursue it during upwards of forty years—are the most extensively known, and comprise, in addition to the main apparatus, a contrivance for adjusting the coulters to distances apart from each other $4\frac{1}{2}$ inches and upwards,—a manure-box and cups, for the deposition of special manures along with the seed-corn,—a contrivance for sowing small seeds simultaneously with drilling in manure and seed-corn,—a swing-steerage for enabling the man in attendance on the machine to move the coulters to the right hand or the left, so as to keep the straight and parallel lines for sowing the seeds,—and various improvements in the barrel, the gearing, the wheels, and other parts. "The Suffolk drill," says Mr. Ransome, "is now the kind in the most general use throughout the kingdom, and is adapted for drilling corn either on level lands or on ridges, and on all descriptions of soil. It is furnished with independent levers, by which the coulters are each readily and separately made to avoid any rocks or irregularities of the ground, and a press-bar, extending over the entire width of the machine, to force the coulters, in case of need, into hard ground, with a varying degree of pressure, according to the texture of the soil. The coulters can be set so as to drill the corn at any width, from four inches to a greater distance; they also, if required, readily allow of the introduction of the horse-hoe; and, from being placed in double rows, they admit, when at work, large stones to pass between them of a size that, under the old plan of placing the coulters in one line, would break or stop the machine. The most complete drills are furnished with the 'swing steerage' before referred to, by which the drill-man keeps the rows at exact or even distances from those which have been previously drilled. The 'corn barrel' is made to deliver from two pecks to six or seven bushels, or strikes of seed, per acre; and they are furnished with an additional barrel for drilling turnips and mangel-wurzel. These barrels, by a simple yet efficient 'regulator,' are kept on unequal hilly ground at the same level; so that the grain is evenly delivered, in whatever situation the drill may be placed. The weight of these drills necessarily varies with the number of coulters,—ranging from three to ten cwt. They are drawn, according to circumstances, by one, two, or three horses. The sliding axletree, allowing the addition of any number of coulters, adapts the drill to different breadths of land."

Garrett's drill for general purposes is a highly improved variety of the Suffolk drill, together with additional contrivances for giving it both nicety of execution and a wide range of adaptation. It is well and truly described as follows in the Catalogue of its patentees and manufacturers, the Messrs. Garrett of Leiston in Suffolk; and we need only premise that a picture of the machine is given in *Plate LVII.*, and a copy of the diagram referred to in the description in *LVIII.*:—"In order to render it as intelligible as possible, it may be described, first, as a drill for artificial manures and corn or seeds,—secondly, as a simple corn or grass seed drill,—and thirdly, as a turnip or mangold-wurtzel seed and manure drill. In the first place, it is adapted to drill corn or seeds, with or without manure, in any required quantities, and at any distance apart. Corn may be deposited down separate conductors from the manure, or through the same pipes, either mixing them together, or separating them by a portion of mould being placed between the manure and seed, by rakes, or drags, provided for that purpose. In order that a continued and regular supply of manure may always be falling from the manure box, a double-actioned stirrer is introduced into it, having a perpendicular as well as a revolving motion, by means of which the manure (which in the drills hitherto in use, frequently clogged and hung back in the box, so much so as to require the attendance of a person to prevent it) is constantly disturbed and pressed

forward into the department for the depositing barrel, causing an equal distribution in exact quantities of the most coarse or badly prepared artificial manures, or well rotted farm-yard dung, mixed with a small proportion of soil or ashes. It is likewise desirable to be able to regulate the delivery of manure as the drill travels, as in going over several acres of land, many portions may be found much richer than others, especially in places where the better soil has been washed (by continued wet) off the hills into the valleys. To ensure this variation of delivery, a slide is placed before the mouth of the manure box, worked easily up and down by turning a small wheel at the back of the drill, so that without stopping the progress of the implement, the man in attendance may alter the quantity as occasion may require. The ends of the drill boxes are made of iron instead of wood, allowing the travelling wheels to run half the distance from the outside coulters at which the others are set, and so returning in the same wheel-marks that they made in going the contrary way of the field, to leave the rows all the same distance apart. This improvement extends also to making drills to cover half-rod lands without the necessity of an additional part to put to it in the field; the full spread of the drill wheels outside, being no more than will admit of its passing through gateways of the ordinary dimensions, viz. 8½ feet. The iron cill, or side frame, is much more durable than when made partly of wood and partly of iron, and affords a ready mode of altering the height of the box to receive the different size cog wheels, as the upright centre, upon which the box rests, is raised or lowered by a screw, numbered to correspond with the teeth in the wheels, so that no difficulty can arise in their being adjusted and kept in proper gear with the greatest precision. As a more convenient and easier method for the man in attendance to raise the manure box, when full, in and out of work, a compound lever is applied, by means of which, less than half the power formerly necessary for the purpose will now suffice; the attendant may easily throw both boxes when fully loaded with manure and corn, in and out of gear, as the drill travels.—In the second place, we come to the drill when used simply for corn or grass seeds. When the implement is required for either of these purposes only, the whole of the manure apparatus may be removed, leaving it a light corn and seed drill. The merits and form of the Suffolk corn drills are familiar to agriculturists generally; it remains therefore but to point out the latest improvements which have brought it to its present state of perfection, and classed it among the most complete implements of agriculture. Among these may be enumerated as the principal, the simple apparatus provided to ensure a regular delivery of the seed when going up or down hill. In descending a drill has a peculiar tremor, and a tendency to go faster than when ascending, giving greater velocity to the delivering cups, and consequently throwing more seed down the conductors. To remedy this, and to render the delivery from the barrel as uniform as possible, two cog wheels of different speeds are placed, one on each end of the barrel; either of which may easily be put in and out of gear, as required, and worked from alternate ends,—the small wheel when going up hill, and the large wheel when going down. The seed-engine accompanying this drill is adapted to sow at the same time with spring corn, or may be used as a separate implement for grass seeds broad-cast, or turnips and mangold-wurtzel in rows. In order to ensure an equal delivery of the different kinds of seed, the box is partitioned off into two departments, one for heavy seeds, such as clover, trefoil, &c., and the other for the lighter seeds, such as rye-grass; the former being delivered from cups, and the latter from brushes, down the same conductors with it. Thus the required quantities of each seed are nicely mixed and evenly sown all over the land, and may be regulated by turning the screw at the end of the box for rye-grass, and changing wheels on the cup barrel for clover, &c. By the new steerage machinery which acts as a fore-carriage to the implement, a man may keep the rows of corn perfectly parallel with the preceding course of the drill. This is done by a man holding the steerage handle and keeping the small fore wheels in the tract of the former large one; this, with a little practice, is very easy, and will amply repay, by the perfect regularity in the crop, affording the greatest facility for the horse-hoe going between all the rows of plants, and with equal precision, where the drills join in their different courses through the field. The swing steerage, at a less cost, and managed without an additional attendant, is amply sufficient where the drill covers each stetch, or land, in twice.—Lastly, as a turnip and manure drill, it may be used to suit all methods of cultivation, whether on flat lands, or ridges, as the axle-tree may be made to slip, so as to alter the sizes to the different widths of ploughing. The distances of the rows may be varied at pleasure. The manure is deposited in a continual stream down the large conductors in any required quantities, and covered with the drags, or rakes, with soil to any depth before the seed (which passes through different pipes) is sown upon it; the seed is then lightly covered with mould by chain harrows suspended from the end of each lever. These drills are also made with an addition to drop the manure and seed at intervals, through separate conductors, instead of a continued stream, by means of which, expensive manures may be much economised, one-third, or half the quantity generally used, being by this means sufficient to afford every plant its full proportion of nourishment."

Lord Western's drill is modelled remotely on Cooke's drill, and proximately on the improved

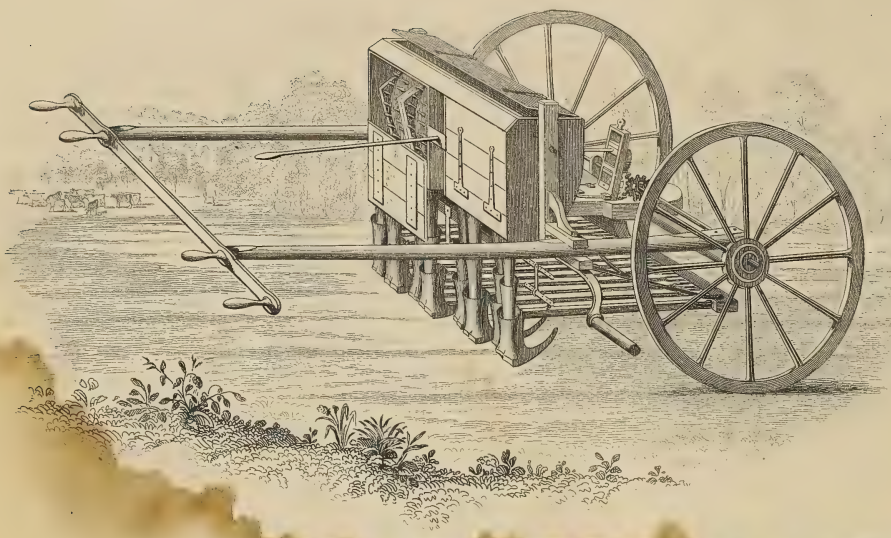
lever varieties of the Suffolk drill; and it comprises improvements for which a patent was taken out in the year 1838. These improvements are, first, the application of improved metallic hinge-joints to the moving levers, so as to ensure their continuing parallel with each other, and in a line with the course of the machine; second, the addition of a pair of thin edged wheels and a fore axle-tree to the machine, by which it can be guided with certainty in any direction; third, a peculiar apparatus for steering the machine, consisting of a shaft passing through a socket, fixed in a plummer-block to the foot-board, its outer end being attached to the fore-axle by a universal joint, the other end having a wheel with handles fixed thereon, by which the machine is readily steered in its course; and fourth, the application of improved iron sockets to the sides of the levers, as a means of fastening the coulters, intead of weakening the levers by passing through them. This implement also admits of horse-hoes being substituted for the drill-coulters; and it performs well the work of horse-hoeing among young plants.

The Scotch drill comprises a number of varieties, differing from one another principally in size, and sowing from five to eleven rows. It is mounted on two wheels, and derives from one o them the motion for turning its machinery of distribution. Its discharging apparatus comprises a line of small thin-toothed wheels, revolving within the seed-chest,—a series of orifices beneath the wheels, for allowing the seeds to drop through which are brought down by their revolution,—and a number of tubes, corresponding to the number of rows which the machine can sow, for catching the seeds from the orifices, and conveying them down to the chambers of the coulters. A chain passes from the horse-shafts under the seed-chest to the hind-bar, and is there hooked or let go by the conductor at pleasure; and this assists him to keep the coulters in the ground. A marking-bar is attached to the machine, and traces a streak in the soil; and along this streak the horse is made to walk in the returning bout in order to equalize the interval between the bouts. Except in cases where the whole field is tilled quite flat, this machine, in consequence of the coulters being fixed, is best adapted for sowing across the ridges. The varieties of it which have only five or six tubes are drawn by one horse; and those of larger size are drawn by two.

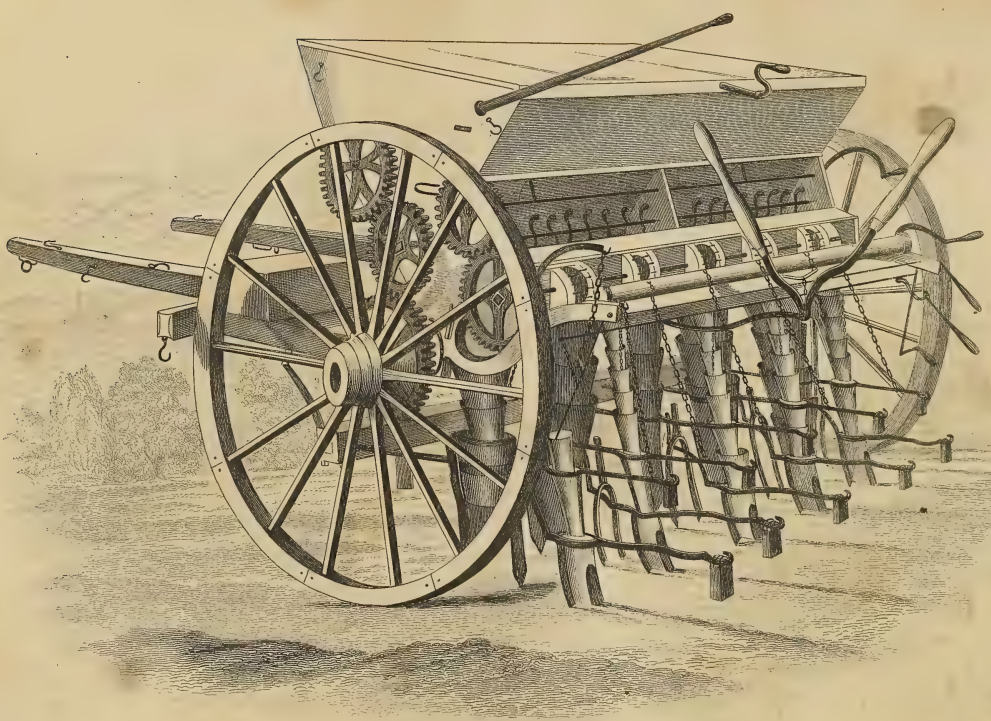
Morton's drill was invented about the year 1828 by Mr. S. Morton of Edinburgh. It is one of the simplest and cheapest of the corn-drills, and at the same time may bear comparison with the best. A figure of it is given in *Plate LVII.* It has a large wheel, with an universal joint; and is fitted with brushes and shutters. "Three hoppers are included in one box; and the seed escapes out of all the three by the revolution of three seed-cylinders upon one axle; and drills of different breadths are produced simply by the shifting of a nut that fixes a screw moving in a groove in the under frame, by which the distance between the two outside conductors and the central one (which is fixed) can be varied from 9 to 10 or 11 inches; and that the two small wheels may always be at the same distances respectively as the conductors, there are two washers (hollow cylinders), an inch in breadth, on the axle arms of each, which may be transferred either to the outside or inside of the wheels so as to make their distances from the outside conductors 9, 10, or 11 inches respectively also. The small wheels may be raised or depressed, so as to alter the depth, at which the seed shall be deposited, by the action of a wedge, which retains the upright part of the axle in any one (at pleasure) of a number of notches, which are made similarly in both, and which are caught by an iron plate on the upper side of the arms which carry the axles. This machine may be still further improved by increasing the number of conductors to five, instead of three, the latter number giving too light work to the horses."

The Bedfordshire drill is a simple and ingenious machine, and possesses an eminently advantageous arrangement for the directing of its motion and the controlling of its work. A figure of it is given in *Plate LVIII.* It was invented by Robert Salmon of Woburn; and obtained about thirty-five years ago the premium at the Duke of Bedford's annual sheep-shearing; and it was afterwards improved, first by two brothers of the name of Bachelor, at Lidlington, in the vicinity of Bedford,—and next by several of the present manufacturers of it, particularly Hensman of Ampthill, Hensman of Woburn, and Smith of Kempston, in Bedfordshire. "The seed-box," says Mr. Ransome, "is suspended upon two centres, one at each side; on these it swings so as to keep its level position as the drill moves up and down hill, or over ridges. Sometimes, instead of the box being made to swing upon centres, it is fixed so as to be altered, as occasion may require, by an adjusting screw and crank placed in a convenient position for the drill-man to regulate. The seed-corn is taken up by iron cups fixed on circular plates and delivered into funnels, from whence it descends to the ground; these plates are centred upon a spindle, which revolves by being connected with the nave of one of the carriage wheels. The coulters are forced into the land by an equal pressure upon each from the centre of the carriage, on which nearly the whole weight of the drill rests. The steerage is effected by a pair of light wooden bars, attached to the axle on which the carriage wheels run. These have a cross bar at their ends, to which small handles are attached, so that the man may guide the drill to a nicety, whether he be at the right or left side of it. Drills on this principle of steerage are made with four, six, or eight coulters; the two larger sizes are in general use in Bed-

Bedfordshire Drill.



Garretts New Drill (with Manure) for Turnips or Mangel-Wurzel.



Engd. by G. H. Swainston, Edinr.

A. Fullarton & Co. London & Edinburgh

fordshire: those with six coulters are considered the best for heavy or hilly land; those with eight coulters for light and level lands. The Bedfordshire drill, which has been thus described, is an exceedingly useful little machine for sowing corn; but it is not suited for the combined purpose of sowing manure and corn at the same time, as the weight of the additional box, when first charged with manure, would be so great as to press the coulters much deeper than is advantageous for depositing the seed, and when nearly emptied, the converse would probably be the case. The total weight of the machine, with the additional loaded manure-box, would also render it unwieldy for a man to turn at the ends of the land. Robert Maynard, of Whittlesford, Cambridgeshire, an ingenious mechanist, to whom the agriculturists are indebted for several improvements in drills and other machinery, has, by the simple contrivance of placing a roller immediately in advance of each coulter, remedied this defect, as these rollers not only prepare the surface of the soil for the most favourable operation of the coulters, but at the same time secure their penetrating the ground to a uniform depth. In his drill the seed-box is a small compartment in the manure-box; its total weight, when loaded with about five bushels of manure, the quantity it is calculated to hold, is not much more than that of an ordinary corn-box; and by placing it somewhat more in advance than the common seed-box, the operator is relieved from any undue weight, which is thus thrown upon the wheels."

Grounsell's drop-drill was patented in June 1839. It deposits seed-corn or pulse-seeds and manure at intervals in drills, and can be made to vary the distances between the intervals at pleasure. A circular iron-ring is fixed about midway between the nave and the rim of the carriage wheel; a number of holes in this ring carries a series of studs, which may be varied according to the length of the desired intervals; and the valves for the delivery of the seeds and the manure are opened by the successive studs in revolution, and immediately shut again when each stud passes. The seeds and the manure, also, are worked into the funnels, not as in other drills with cups, but with projecting arms or shovels.

Hornsby's drop-drill was patented in November, 1839, and performs the same kind of function as Grounsell's, but with a widely different mechanism. "The manner of regulating the delivery is by having a coulter of a peculiar form inside, in which a circular box revolves on an axle which passes through one side. This box is divided into compartments closed by small doors, which are kept shut by a spring to each; the compartments in the box are supplied through a series of funnels, the end of the lower one entering one side of the box below the centre. On the machine being moved forwards, this box revolves by means of appropriate cog-wheels; and as each spring arrives at the ground, the door to which it is attached opens, and the contents of that compartment are deposited, to be again replaced when it arrives at the part of its rotation at the end of the funnel, and so on successively."

Garrett's drop-drill is a modification of the drill for general purposes, so constructed as to deposit seed and manure at intervals on ridges or flat ground; and—as well as the general drill—it comprises a number of sizes and varieties. "The merits of these drills," say Messrs. Garrett, "are important in economizing expensive manures, as one-third of the quantity generally used will now suffice for the crop. By this novel and effectual contrivance of dropping the seed and manure in heaps, at intervals, every plant is nourished with its full proportion of the manure. Prior to our invention, no drills were made but what deposited in a continual stream, or dropped the seed and manure out of the pipes together mixed in one heap, so that when strong manures were used, they were almost certain to spoil the germ of the seed, and prevent its vegetating, thus offering at once a great and fatal objection to their use. To remedy this our present patent has been taken out, and is for correctly dropping the manure and seed separately at any required intervals, so that in one process the manure is dropped at intervals, at any required depth below the seed and covered with mould; then follows the seed-conductor, and lodges in any minute quantity patches directly above the manure, leaving a small portion of mould between them. By the new steerage machinery which is applied to these drills, and which acts as a fore-carriage to the implement, a man may keep the rows of corn perfectly parallel with the preceding course of the drill; this is done by the man holding the handle and keeping the small fore-wheel in the track of the preceding large one; this, with a little practice, is very easy, and will amply repay by the regularity afforded to the crops, besides the facility it affords for the horse-hoe going between those rows of plants where the drill joins in its different courses through the field." The figure of the drill for general purposes in *Plate LIX.* represents that drill set for turnips, the two levers on the right hand being to drop the manure and seed, and the three on the left to drill them in a continual stream,—and it is shown in these two ways in order to illustrate more clearly the merits of their respective plans; but, of course, when the implement is in use, all the levers are either used to drop, or all to drill in a line.

Rham's sowing-machine—invented by the late Rev. W. L. Rham of Winkfield, and patented in November, 1841—is rather a dibbler than a drill; yet it is suited alike to wheat and pulse and some other crops, and was designed by the inventor so to drill and dibble seed upon flat and well-prepared land that any field sown by it, no matter how extensive, should present the neatness and regularity of a highly finished garden; and it is

therefore well entitled to notice in this place. The judges at the Royal Agricultural Society's show at Liverpool in 1841, spoke of it "chiefly in its capacity of a dibbler of seed and manure," and reported upon it as follows:—"The operative part of the machine is suspended upon an iron carriage having four wheels, the two hinder ones being fast upon their axle and turning within it. On this axle is a spur-wheel, giving motion to a pinion on an intermediary axle, which carries a wheel geared into a second pinion fixed on its axis, having six cranks arranged spirally. The velocity given to the axis is such that the cranks make one revolution for every six inches of the circumference of the hind wheels, or whatever is the distance desired between the dibble-holes. The radius of each crank is such that this distance shall be equal to the circumference described by one revolution. Thus the space described by every crank coincides with that passed over in the same time by the hind wheels; and as the cranks turn, during the half of a revolution, in an opposite direction to that of the wheels, the result of this compound motion is a pause or rest of short duration, at the point where the crank in its rotation commences to retrograde from the line of progress of the machine, *i. e.* at the lowest point, and when the dibbles are in the ground. The crank raises the dibbles up and down by means of connecting rods and levers, which double the vertical without increasing the horizontal motion; and in order that the point when in the ground, may be perfectly stationary, it is made the centre of motion while the machine progresses; and to enable it to retain that position for a sufficient length of time for the purpose of leaving a hole truly vertical, the dibbles move between checks in the rod which connects it with the crank, and which has a spring to restore it quickly to its proper place as it rises out of the ground. During therefore the entire time occupied in its piercing the hole and being withdrawn from the soil, the dibble retains its perpendicularity. By an ingenious and simple contrivance, a slow rotatory motion about its own axis is given to the dibble, by which means its point may be said to bore into the ground, thus assisting in the formation of the hole; and by the same action the dibble is cleared of any adhering soil, and the hole left firm and clear. The seed-valve consists of a cylinder, with a cavity in it of dimensions sufficient to hold one or more seeds. This cylinder is tumbled over, and the seed discharged into a recipient of the shape of a quadrant, from which it is pushed out, when the cylinder returns to its first position and takes in a fresh supply. As this motion is sudden, the seed is surely delivered, even when rather damp: when the cylinder is delivering, the quadrant is receiving, and *vice versâ*. The delivery of manure is effected by a similar apparatus, only of a larger size, the valves being furnished with brushes or other means to remove the superfluity. The valves are connected with the dibbles in such a manner as to deposit the manure and seed in the hole last formed, whilst the dibbles are stationary in the advancing one. The dibbles bore their holes in shallow drills made by the pressure and sliding action of an iron shoe shaped like a boat, and forming a smooth furrow. The whole of the machinery is supported by an iron frame, one end of which rests on trunnions attached to a projecting part of the back of the carriage. It is suspended at the other end by a cross shaft carrying two pinions, working in arcs of circles fixed on the frame, so that it can be raised or depressed at pleasure, or elevated clear of the ground by one turn of a winch. At the same time, the pinion connecting the machinery with the hind wheels is put out of gear, and the whole can be moved about on the carriage. The implement is steered in a manner somewhat similar to Lord Western's drill." See the articles DIBBLE and DIBBLING.

The broadcast sowing-machine, in one of its most improved forms, for sowing seeds of corn and grasses, is described in the article BROADCAST SOWING. This machine is not much used in England, but is extensively and increasingly used in the best arable districts of Scotland. Its great recommendations, which give its work a preference to hand-sowing, are the saving of seeds, the regularity and certainty of their deposition, and the prevention of all the bad consequences of unskilfulness or carelessness or conflicting with the wind on the part of a hand-sower. The first broadcast sowing machine ever known in Scotland was introduced in 1816 from Yorkshire; and the first ever manufactured in Scotland was made in 1817 by Mr. Lowrie at Edington in Berwickshire. "In the early application of the broadcast machine," said Mr. Slight in 1844, "it was mounted on two wheels; but a few years experience pointed out the advantages of a third wheel, which was applied to it by Messrs. Scouler of Haddington about the year 1830, the third wheel being applied as a swivel or fore-carriage. The carriage is still subject to considerable variety of construction; but these varieties are not of a nature to alter its general character. A carriage of nearly triangular form is very generally adopted, the apex being in front over the swivel-bar. A rectangular carriage is also very much employed; and this is the most workmanlike construction, though perhaps not the cheapest, but it is withal the most convenient and useful form. As regards the general construction, an important improvement has been introduced within the last six years; this is the cutting of the seed-chest into sections. The chest is usually made 18 feet long, which being far beyond the width of any field gate, produced a necessity for changing the position of the chest when passing through a gateway. It was therefore the practice to lift the chest from its working position parallel to the axle of the machine, and deposit it parallel to the horse-shafts until it had passed through the

gate. This was clearly both imperfect and inconvenient, and these defects gave rise to the cutting into sections, the middle part being 9 feet, and the extremes each 4½ feet, so that when the latter are folded up, the extreme length of chest is 9 feet."

Dudgeon's sowing-machine was invented about twelve years ago, by Mr. Dudgeon of Broomhouse, East Lothian, and is an amplification of the broadcast machine with additions of roller and harrow to perform the processes of sowing, rolling, and harrowing grass-seeds at one operation. The fore and hind bars of the top frame have a length of about 7 feet 4 inches, and are set at the distance of 2 feet apart. The horse-shafts are bolted down to these bars, and have the same length as any ordinary horse-shafts, but are prolonged into extension-bars, which are bolted to their ends. The seed-chest occurs first, the roller next, and the harrow last. The seed-chest has a length of 6½ feet, and is appended to the lower side of the horse-shafts, immediately in front of the fore-bar, and may be fitted up in all respects similar to the common broadcast seed-chest, the spindle which carries the small discharging toothed wheels being put in motion by a belt or a chain passing over a pulley, 12 inches in diameter, on the projecting end of the spindle; the belt or chain receiving its motion from another pulley of 9 inches diameter, placed on the axle of the roller. The roller is also 6½ feet in length, and is about 18 inches in diameter, though this is not imperative, nor is the material of any essential importance. It is supported by its journals in two semicircular bars of malleable iron, or of cast iron, bolted to the extremities of the fore and hind bars. From the semicircular bars proceed also two stays for the further support of the seed-chest. The harrow is suspended immediately behind the roller. It consists of two frames, each 3½ feet in length, and 1 foot in width, which are jointed end to end, and form a harrow 7 feet in length, with only two rows of tines. The tines are set at 2½ inches distant; and, as those of the one row alternate with those of the other, they make a rut at every 1¼ inch. The direct suspension of the harrow is effected by means of chains from a moveable bar which, being jointed at one end, is capable of being raised aloft from the horizontal position to any requisite or desirable point of elevation, and retained there by a pin passed through a quadrant over which the bar moves; and by this means the harrow is regulated as to depth,—while by means of a link from the semicircular bars, and by a chain from the extremity of the extension bars, it is duly stayed in a proper position, and at the same time has sufficient freedom of swing to ensure its useful effect. A joint at the middle of the harrow allows it to accommodate itself to the rounding of the ridges when required; and a lever in the middle of the top frame is, through its connexion with another lever on the back of the seed-chest, used for opening and shutting the orifices, and for regulating the discharge of the seed, by moving a long slide plate in the usual manner.—Fullarton's sowing-machine also performs the whole process of depositing grass-seeds at one operation; and it differs from Dudgeon's only in the arrangement of the parts,—the order of its processes being rolling, sowing, and harrowing.

Turnip drills exceedingly vary in size, structure, and complexity. Some are small hand barrows, and others are large horse-drawn machines; some are the simplest of all sowing machines, and others are nearly or quite as complex as the most elaborately constructed grain drills; some sow only single rows, and others sow two rows, or several, or many; some sow in continuous streams, and others at intervals in the drop manner; some sow only seeds, and others both seeds and manure; some are suitable only or chiefly for turnip-seeds, and others are suitable also for corn seeds, grass seeds, or other field seeds. One class have grooved cylinders, with a size and a mode of action suited to the minuteness of the seeds, and make their depositions through tubes defended at the point by rut-making coulters; another class have revolving cylindrical boxes of iron or tin, perforated in a line all round for the passage of the seeds, and sheathed in an iron or tin plate, also perforated with sets of holes, and capable of such slight shifting of position as to regulate the amount of discharge; and a third class imitate the peculiarities or aggregate structure of some of the best large grain drills, of which, in some instances, they are mere modifications.

The common drill-barrow is a small light wheel-barrow, driven by hand, and sows turnip-seeds or other small seeds in a single row. The seed falls from the seed-box on a wooden or metal cylinder below, and is regulated, in the quantity of the fall, by a slide in the box; it afterwards lodges in several cavities in the circumference of the cylinder, and passes down thence into a tin funnel below; and it is made to descend in an uniform stream by means of small brushes in which the cylinder turns. The motion is communicated from the wheel to the cylinder by a chain on two pulleys placed on the axes.

Bennet's turnip and grass seed sowing-machine has a long box fixed transversely on a barrow, and connected by light gear-work to the barrow-wheel. In the box are a number of brushes fixed on a spindle, and running the whole length, which revolve, as the machine progresses, against perforated plates of copper, and carry with them the seed in such quantities as the operator desires or has set the regulating plates to let pass.

The one-horse, two-row turnip-drill is the machine most extensively used for sowing turnips in the best arable districts of Scotland. It moves on two concave rollers, generally of cast-iron,

which serve both to consolidate the drill and to give motion to the seed barrels; and they are self-adjustable to the width of drill by sliding on their own axis. The seed barrels are made of tin, and have small orifices of three sizes for discharging the seed; and the tubes which receive the seed from the orifices terminate in the chamber of the coulters, and deposit the seed in the ruts which the coulters form. Two small rollers are occasionally used, attached to the seed-box frame, for covering the seed.

Geddes's turnip-sowing machine is an improved form of the one-horse two-row turnip-drill. It was invented by Mr. Geddes of Cargen-Bridge in Dumfries-shire, and was first exhibited in 1837. A figure of it is given in *Plate LIX.* The improvements occur, not in the general construction of the machine, but principally in the substitution of a seed-box and distributing roller for the tin-plate seed-barrel, and in the communicating of motion from the rollers in which the machine moves to the distributor. The horse-shafts are bolted down at their hinder end upon a bed-plank; the handles also are jointed to the bed-plank, and can rise or fall within the guidance of sheers affixed to its hind edge; and two inverted standards are attached by bolts to the ends of the bed-plank, and connect it with the travelling-axle. The curved rollers, on which the machine travels, are, as in the common two-row turnip-drill, 16 inches in length, and 14 inches in diameter at the ends, and diminish to 8 inches in the middle; and they consist of cast-iron, with cross arms at each end, and have a rod or axle, common to both, passing through them and the standards. A pendant iron V-stay supports the middle of the axle; and the length of the bed-plank and the axle is such as to afford space for the rollers to shift to right or left, accommodating themselves to the varying width of the drills. The seed-box frames are also appended to the axle, and move laterally with their respective roller; and the seed-boxes are placed on a small platform attached to the arms of the frame. The motion which the rollers acquire by the travelling of the machine is communicated to the seed-distributor through trains of small wheels; and these are enclosed in a case, to prevent earth from falling into their teeth; and the first wheel of each train is connected with the end of its roller, and the last is placed upon the axis of the distributor. Small rollers are attached to the frames, similar to those which are used in the common two-row turnip-drill, for the purpose of giving a slight cover to the seed; and here they serve also as regulators of the depth to which the seed rut is formed, and therefore they can be raised or lowered by shifting their axes, and are provided with scrapers to remove any adhering earth. The seed-box frames are attached to the handles by a chain; and by means of this, they can be lifted from the ground at pleasure. The seed-box is a bowl of 7 inches in diameter and 5 inches in depth, and opens at the bottom into a space which is filled with the distributing roller. This roller is of brass, and about $1\frac{1}{2}$ inch in diameter, and has a groove of one-tenth of an inch wide running round it. A slider has a tongue adapted to fit into the groove, and is fixed by means of a screw to suit any required quantity of seed that it may be desirable to sow per acre,—the quantity of seed distributed being proportioned to the extent of opening left between the point of the tongue and the bottom of the groove.

The two-row turnip and bone-dust sowing-machine makes a simultaneous deposition of the seed and the manure, and is used in the best arable districts of Scotland. It is drawn by one horse, and has the distance between the coulters regulated by hand-gear. It is mounted on two wheels, which serve to turn both the seed and the bone-dust apparatus. The former consists of the common tin seed-barrels; and the latter comprises two wooden hoppers, with each an enclosed wide-toothed or notched wheel, whose revolving motion discharges the bone-dust contained in the hopper into a tube which terminates, in common with the tube from the seed-barrel, in the chamber of the coulter. The regulation of the discharge of the bone-dust is effected by means of a slider which enlarges or diminishes the passage from the hopper.

Nicol's turnip and bone-dust sowing-machine is one of the oldest combinations of mechanism for simultaneously depositing the seed and the manure; and it considerably resembles the common two-row turnip and bone-dust sowing-machine in general structure; but it has a different arrangement of parts, and different modes of communicating the motions. It travels on one large roller and on a fore-wheel without a swivel-bar; and the former gives motion to the sowing apparatus; and the adjustment of the coulters is not self-acting, but is effected by hand-gear.—Hamilton's turnip and bone-dust sowing-machine possesses the same properties as the preceding, but is differently arranged.

Crosskill's improved turnip and manure drill is made of two kinds,—the one for sowing one drill and the other for sowing two drills. It sows, in rows 24 inches apart, quantities of seed, graduated by the number of cogs upon a regulating wheel, from $1\frac{1}{4}$ to $2\frac{3}{4}$ lbs. per acre; and it sows, with the same cups, from 20 to 40 bushels of bones or other pulverized manure per acre. By drawing the box with the iron lever fixed to it to the hindmost part of the drill, it sows more, —and by drawing it forward, less; and a slide in the box is also drawn up or down to assist in depositing the quantity required. The iron lever on the side of the machine is likewise used to throw the wheels in or out of work.

Garrett's lever ridge-drill for turnips or mangel-wurzel with manure is made with two coulters, and is intended for ridge ploughed lands,

having the same improvements and advantages, in the manure department, as Garrett's drill for general purposes, with the improved slides to regulate the quantity of manure placed directly under the management of the attendant who follows the drill, and may be altered while the implement is proceeding in its work, admitting larger or smaller quantities, as may be required on hilly lands, or various qualities of soil. In order to accommodate the drill to irregular ploughed ridges, a pair of rollers are attached to a fore carriage, so as to form and press the land properly for the deposit of the manure and seed; and what has hitherto been found a difficulty, of keeping the depositing coulters on the top of the ridges, is remedied in this, by the levers being easily steered by a parallel movement, so that the seed coulter advances in the exact line of the manure coulter. The rakes add greatly to the effective working of the drill,—those foremost filling up the channel left by the large manure coulters, and thus permitting the seed coulter to make its work in fresh stirred mould, directly above the manure,—and the latter rakes will sufficiently cover the seed, leaving a slight dip for retaining the smallest quantity of moisture.

Garrett's lever drills for turnip, mangel-wurzel, and other seeds with manure may be used to suit all methods of cultivation, being made to work with any number of levers, having axletrees to slip, so as to alter the sizes to the different widths of ploughing, and parallel swing or fore carriage steerages, enabling the man in attendance to guide the coulters or drill, without depending on the driving of the horses. On stetch or broad work, the rows of seed may be deposited from 12 inches to any wider space. In these drills the turnip and mangel-wurzel seeds are taken up separately by the cups, but deposited together down the conductors, so as to prevent any unequal mixture of the seeds. The novelties and improvements in the manuring machinery are the same as in the drill for general purposes, with the manure box and apparatus made large, for depositing any quantity of every kind of artificial or well rotted farm-yard manure.

Crozier's turnip-sowing-machine, with apparatus for depositing liquid manure with the seed, was invented nearly thirty years ago by Mr. Crozier of Alnwick. It differs little in the construction of its sowing part from the common two-row turnip-drill; but is distinguished by carrying a liquid manure cistern, fitted with cocks and tubes, by which the liquid can be deposited along with the seed.

M'Naughton's sowing-machine for carrots and turnips was invented in 1833 by Mr. M'Naughton of Irvine. It is intended principally for sowing carrot; and the seed-distributors are accordingly adapted to separate and discharge that peculiarly adhesive seed. This is performed by the revolution of small spiked wheels in each seed-box, aided by a separate and smaller wheel of the same kind revolving in the orifice of the seed-box. By a slight change in the distributing apparatus, the machine is converted into an efficient turnip-drill.

Liston's turnip drop-drill was invented in 1835 by Mr. Liston of Blairgowrie. Instead of sowing continuously, this machine was intended to deposit a portion of seed and manure together, at stated intervals, whereby a saving might accrue, both in the seed and manure, and the first thinning of the braird might be dispensed with. The construction of the machine differs both from previous turnip and bone-dust sowers, except in the depositors; these consist of a short double conical roller, which forms the groove or rut, in a continuous form, for the reception of the seed and manure, and this followed by a short cylinder, partly incased in a cover. The cylinder is chambered on the periphery; in these, certain quantities of the seed and manure are collected; and as the cylinder revolves and the machine progresses, these little collections are discharged at the proposed distances. In practice, however, it was found that the chambered cylinder did not deliver its contents at intervals, but nearly uniform, except when the machine travelled so slow as to be ineffective.

Nicol's turnip and bone-dust drop-drill was invented by Mr. Nicol of Guildy in Forfarshire in 1840. Its construction is nearly the same as that of Liston's, except the dropping apparatus. This consists of a raised fillet encircling the front rollers, and having also obtuse dibbles proceeding from it at nine-inch spaces, which, while the roller levels the top of the drill, forms also a smooth channel, with dibble holes at nine inches apart, along its surface. Into this channel the seed and bones are deposited continuously; but an iron instrument or scraper follows close behind, having a protuberance that follows in the channel of the drill; this member sweeps the bones and seed before it till they fall into the first dibble-hole, and so on.

The common bean-drill sows only one row at a time, and is mounted like a wheel-barrow, and is so light as to be easily pushed forward by the hand. A groved cylinder works in the bottom of its seed-box; and at each revolution of the cylinder, a quantity of seeds, dependent on the size of the grooves, is carried round, and falls into a tube at the bottom, and is conveyed through this to the ground. Motion is conveyed to the cylinder from the barrow's travelling wheel by means of cranks.

The bone-dust sowing-machine is employed for depositing bone-dust or other granulated manures in drills, and is adapted to serve three drills at each turn. The bone-chest is mounted on two wheels, one of which gives motion to the three distributing wheels placed inside the chest; the revolutions of the latter give out the manure to the sheet-iron tunnels, which deliver it into

the furrows previously prepared by the plough. The quantity to be discharged is regulated by sliders which lie over the orifices. In depositing manure by this machine, it is laid in the furrows between the first-formed drills, and is then covered up by passing the plough along the drill and cleaving it. After this operation, the seed is deposited by the common turnip sowing-machine. The bone-sower may be drawn by one horse.

The English manure-drill is a moveable, facile, and very efficient appendage to the common lever corn-drill; and can at any time be adjusted, and put into working trim, by any husbandman. "It is," says Mr. Ransome, "a simple yet accurately-working apparatus for delivering the manure,—which, in the best drills, it does with great evenness, and in quantities varying, as 'the slip' is placed, from six to eight bushels per acre. In the best-drills, also, a very important improvement has been made within the last few years, which consists in the use of separate coulters for manure and seed. The manure is now deposited according to the mode preferred by the cultivator, not only from two to three inches deeper in the ground than the seed, but from ten to twelve inches in advance of it, so as to give the soil time to cover the manure before the next coulters deposit the seed." This improvement exists in all its amplitude in all Garrett's seed and manure drills.

Crosskill's improved portable manure-drill is a one-horse skeleton cart, surmounted by seed-box and sowing-gear. It serves for sowing soot, salt, guano, and other special manures. It is six feet wide, and contains eight bushels of manure, and sows a comparatively great or small extent of land per day according to the speed of the horse. The acreable quantity sown is regulated by the position of the seed-box and the extra cog-wheels; for according as the box is placed toward a vertical or toward a horizontal position, the quantity per acre is increased or diminished.—*Ransome's Implements of Agriculture.—Gray's Implements of Husbandry.—Catalogue of the Highland Society's Museum.—Catalogues of Garrett, Crosskill, and other principal Implement-Makers.—Annual Register of Agricultural Implements.—Slight's Descriptions of Implements in Stephen's Book of the Farm.—The Society of Gentlemen's Complete Farmer.—Low's Elements of Agriculture.—Rham's Dictionary of the Farm.—The Bath Papers.—Quarterly Journal of Agriculture.—Transactions of the Highland Society.—Journal of the Royal Agricultural Society of England.*

SOW-THISTLE,—botanically *Sonchus*. A diversified genus of plants, of the succory division of the composite order. Four species grow wild in Britain; upwards of twenty have been introduced from other countries; a number of uninroduced exotic species are known; and nine or ten species which recently ranked as sow-thistles are now assigned to other genera. Seven of the introduced species are ornamental, greenhouse, yellow-flowered, evergreen shrubs, of from 2 to 5 feet in height; eight or nine are ornamental herbs, some annual, some biennial, and some perennial, all with runcinate or lyrate leaves, and most with yellow flowers, and about 2 or 3 feet in height; one is a handsome, hardy, perennial-rooted herb, with entire leaves and yellow flowers; and three are respectively annual, biennial, and perennial herbs, with pinnatifid leaves and weed-like appearance.—The stems of the four indigenous species are hollow; the leaves are runcinate or lyrate, and have toothed or prickly edges; the inflorescence is hairy or glandular; the flowers are yellow; and the whole herbage is smooth without, and has a bitter white juice within.—The potherb species, or common sow-thistle, *Sonchus oleraceus*, is one of the most generally diffused of our annual weeds, and abounds in multitudes of fields both waste and cultivated. It has commonly a height of about two feet, and blooms from June till August. Its roots are milky and bitter, but have occasionally been converted into bread; and its leaves are greedily eaten by hares and rabbits, and are sometimes dressed and eaten in the manner of culinary herbs.—The rough species, *Sonchus asper*, is also an annual weed of our fields, and is similar in height and bloom to the common species.—The corn-field species, *Sonchus arvensis*, is a perennial-rooted weed of our corn-fields, and has a height of about 20 inches, and blooms in July and August.—The marsh species, *Sonchus palustris*, is a perennial-rooted indigen of the river-banks of some parts of England, and has commonly a height of from 5 to 8 feet, and blooms in July and August, and makes an interesting and even handsome appearance.

SOY. See Soja.

SPADE. A hand implement used for digging. It comprises a number of varieties; yet, even inclusive of these, is everywhere so well known as not to require any description.

SPADE HUSBANDRY. The cultivation of land by means of the spade, either without the plough or along with the plough. Spade husbandry without the plough is practised in kitchen gardens, in allotment plots, in cottier farms, on rocky grounds, on precipitous banks, and in all other circumstances of tillage where the introduction of the plough is impracticable or uneconomical. The superior power of it to ploughing, on almost all varieties of land of the same natural depth and character as that of ploughed fields, is well known to all classes of cultivators; and consists in greater depth of tillage, in opening a far wider scope for the varying and ramifying of the roots of plants, in effecting a far fuller degree of every kind of subsoil stirring, in rendering the whole soil much more pulverulent, friable, and mellow, and in avoiding all the bad effects of the tread of the feet of horses, and of the pan-forming action of the sole of the plough.

Spade husbandry in conjunction with ploughing makes fully as much use of the three-pronged fork as of the spade, and deals more directly with the subsoil than with the soil, and possesses perfect adaptation to extensive fields and farms, and is capable of great achievements in the way of improving the tilth and produce of much valuable land which maintains a mediocre and stationary character under the action of horse-drawn implements. We cannot better illustrate these points than by presenting an abstract of a recent paper on the subject from the pen of Mr. Cuthbert W. Johnson. "The subsoil plough, to which such an impetus has been given by Mr. Smith of Deanston," says he, "has been tried in much too careless a manner, and with too little discrimination, for it to be universally popular. Its effects, too, on many soils with stiff clay substrata, are neither remarkable in extent nor soon apparent. On such land the subsoil is not sufficiently broken, the earth merely rising or swelling in the trench, and speedily settling to nearly its former firmness. On such soils the spade, or, what is infinitely better, the fork, generally produces much better effects — the soil is more broken, and the subsoil better interspersed with small cavities, to which the air penetrates, and through which the superfluous water of the soil escapes, and the roots of the cultivator's crops extend with greatly increased facility. The rain gradually sinks down to the whole depth of the porous substratum, and from thence to the furrow drains; and, in time of great drought, the deep-moved ground will hold, by capillary attraction, a much greater supply of moisture for the nourishment of plants; so that thoroughly deepening and loosening the soil, not only assists the escape of the superabundant water during heavy rains, but it affords additional means of supplying healthy vegetation with moisture at those times when it is most needed.

"An experiment in fork-husbandry, on a bold scale, was commenced some time previous to 1837, by Mr. Mitchell, in the parish of Wymondham in Norfolk,—and was reported by the late Dr. Yelloly to the British Association; and that portion of his remarks which alludes to the results obtained I will give in this paper, since it answers very completely certain practical questions as to the working of the fork-husbandry which are sure to be proposed by those who have not witnessed the working of the system. The farm of Wattelfield, on which the experiment was conducted, consists of about 317 acres, of which 207 are arable, and 110 in pastures and plantations. The digging was at first carried on with the spade, but this was speedily exchanged for a strong three-pronged fork, of 14 inches deep, and 7½ inches wide, which is found to be more manageable and less expensive than the spade. This fork cost 4s. 6d. instead of 6s. 6d., weighed 8 lbs., and, when worked down, could be relaid at a trifling expense. The digging is effected by taking in about 4 inches of earth at a time, pressing perpendicularly, and getting to a proper depth at two thrusts. The earth, however, is not turned out of the trench to a greater depth than ten inches, although the fork may get down as far as 13 or 14, but that which remains at the bottom in the state of what is called 'crumbs' answers the purpose equally with the earth which is thrown out, of forming a permeable medium for the roots of the plant which is to grow in it. The men prefer working together, in order that their labour may be, as nearly as possible, on the same description of soil; but each takes in about 9 feet in width, so that his work can be easily measured. The plan is to have a breathing about every half hour, and the men never work more than the regular ten hours per day. Digging is, however, more laborious than the usual operations of agriculture, though it is much less so with the use of the fork than when the spade is employed. The labourers work the land in ridges of about 9 feet in width; and the furrows dividing them are sometimes made by the plough previously to the digging, and sometimes by the management of the labourers. The men receive for the ordinary digging after a white crop from 2d. to 2½d. per rod, of thirty square yards, the price varying according to the tenacity of the soil. Where the land is to have a fallow crop, such as turnip, mangel-wurzel, or cabbages (for no part of the farm or the land in the immediate neighbourhood has ever a naked fallow), there is first a ploughing, which is done at a season when the horses can be best spared, and afterwards a digging at from 1¾d. to 2d. per rod. In preparing for a fallow crop, there is also an expense incurred in harrowing and in raising a ridge with the plough, which last is worth about 7s. per acre. The men are paid the usual wages of the neighbourhood at harvest; but as the whole number ordinarily employed are not required at that period, those for whom there is no occasion disperse themselves amongst the neighbouring farmers, with the understanding that they may resume their employment when harvest is over, which they are always happy in doing. The ordinary earnings of a labourer in digging are from 11s. to 12s. per week. It is to be noticed that Mr. Mitchell has always ploughed clover lay for the succeeding crop, not dug it, and that the horses, when not wanted for other purposes, are employed in assisting the diggers in preparing the land for seed. Twenty labourers are kept upon the farm instead of thirteen, who would be necessary under the ordinary system, and five or six horses instead of twelve. As the demands upon these horses, in hay and corn harvest, are considerable, a good proportion of the hay and corn is stacked in the fields where they are grown.

"It is hardly necessary, in support of these facts, to refer to the very considerable and successful extent to which the spade husbandry

prevails in many of the Continental states, such as in the north of Spain, France, and Flanders. Of the last the Rev. W. Rham observes—'The husbandry of the whole of the north-eastern part of East Flanders, where the soil is good sandy loam, may be considered as a mixed cultivation, partly by the plough and partly by the spade. Without the spade it would be impossible to give that finish to the land, after it is sown, which makes it appear so like a garden, and which is the chief cause of the more certain vegetation of the seed. There is also a great saving of seed by this practice, as may be seen by comparing the quantity actually sown in Flanders with that required in other countries where the spade is more sparingly used. In large farms in England, the spade is only used to dig out water furrows; but in Flanders, where the land is usually laid in stetches of about six or seven feet wide, the intervals are always dug out with the spade, and the earth spread evenly (*sifted* as they call it) over the seed which has been harrowed in. The trenches are so arranged that every year a fresh portion of the ground is dug out, and in six years the whole land will have been dug to the depth of, at least, one foot. In the next course, the trench is dug a few inches deeper, which brings up a little of the subsoil; and, after four or five such courses of trenching, the whole soil comes to be of a uniform quality to the depth of from eighteen to twenty inches, a most important circumstance to the growth of flax, potatoes, and carrots. In the Waes country they proceed differently, for they have a soil which, by repeated trenchings, has long been uniform in quality to the required depth; there they regularly trench one-sixth part of the land every year, and plant it with potatoes or sow carrots upon it.'

"If we direct our attention even to those cases where small plots of land are *exclusively* farmed, not gardened, by the spade or fork, the result is still more satisfactory; and here, too, the good effects produced, the strangely enlarged fertility of the soil, is almost entirely attributable to the deep forking. Let any traveller by the south-western railway (to take at once an extreme case) notice the results of deep stirring in some of the little cottage gardens enclosed from the heaths of Woking and Bagshot; let him witness the luxuriant little crops of both wheat and the common culinary vegetables growing in the gardens of these little peasants' nests, all looking as thriving and as luxuriant as possible; and yet this effect is all the work of the deeply penetrating fork or spade. Let the passenger compare these with the surrounding heath-covered lands, and it will be impossible for him to arrive but at one conclusion. The distant cultivator will judge at once of the natural poverty of the soil of Bagshot Heath by its chemical composition. It contains in 400 parts, after being heated to redness, 380 of coarse siliceous sand, 9 of fine siliceous sand, and 11 of clay, oxide of iron, and carbonate of lime. And it is not to the sandy soils that the benefits of fork husbandry are confined. On the chalky soils of Eastbourne, during the last few years, a considerable extent of land has been let out to about 400 little spade-cultivators, holding, as regards extent, in every proportion, from a few square rods to as many acres. One of these, George Cruttenden, a schoolmaster of Willingdon, reports, April 1842:—'The quantity of land I rent is five acres, on the side of the South Downs, at £3 per acre—this, with £10 for my house, makes £25. I have now three cows, a heifer, and a calf, standing opposite to each other, with a road between the mangers for feeding these stall-fed cattle. I am satisfied that I can keep two cows on the same quantity of land, stall-fed, that I could keep one if I allowed it to graze.' It is true that in this last successful instance, Cruttenden keeps a thriving little agricultural school, whose scholars, in return for their tuition, assist him in the cultivation of the five acres,—these yielded him a clear profit of £40 in 1842.

"It is an error into which the farmer very commonly falls, to conclude that there is any material difference in the earthy composition of uncultivated soils and the substratum; for, generally speaking, the only difference between the surface soil and the stratum on which it immediately rests consists in the upper soil containing a larger proportion of soluble and decomposing organic matter. It is only the absence of these from the substratum which renders it, when too copiously mixed with the surface soil, rather prejudicial at first than otherwise; and this is one reason why the fork is preferable in the first instance, of deepening the soil, to the spade or to very deep ploughing, since the fork deepens and loosens the soil, perhaps to a greater extent than either of the other implements, but then it does not bring to the surface so much of the substratum. There is no doubt with regard to the similarity of composition in the different soils and subsoils. The principal mineral in the soil of any district, as Mr. Morton observes, is that of the geological formation under it; hence we find argillaceous soil resting on the various clay formations, calcareous soil over the chalk and oolitic rocks, and siliceous soils over the various sandstones. On the chalk, the soil is white; on the red sandstone it is red, and on the sands and clays the surface has nearly the same shade of colour as the subsoil. And, in fact, we perceive a change in the external appearance of the surface wherever there is a change in the subsoil below. If, then, these are correctly stated facts—if such superior fertilizing effects are produced by the use of the fork beyond those which follow the plough—ought we not indeed to rejoice? Should we not exult that here is opened to the cultivator another source of fertility; one, too, not confined to any par-

ticular locality, not requiring the use of other agents than the sinewy arms of the agricultural labourers? Its general adoption, indeed, will afford a greatly extended supply of field work—labour, too, of the most healthy, the most valuable kind—carried on in the broad light of heaven, far away from the crowds, the diseases, and the other miseries which attend the densely congregated citizens."

SPANCEL. A rope to tie a cow's hind legs.

SPANIEL. See Dog.

SPARAXIS. A genus of ornamental, bulbous-rooted, Cape-of-Good-Hope plants, of the iris order. About a dozen species, besides a number of varieties, have been introduced to the greenhouses of Britain; and they love a mixed soil of sand and peat and loam, and are propagated from offsets. They vary in height from 3 to 15 inches; and they present great diversity in the colour of their flowers. The name sparaxis is derived from a word signifying 'to tear,' and alludes to the lacerated spathes.

SPARGANIUM. See Bur-Reed.

SPARMANNIA. An ornamental, exotic, evergreen shrub, of the lime-tree family. It is a native of the Cape of Good Hope, and was introduced to the gardens of Britain in 1790. It commonly attains a height of about 10 or 12 feet, and blooms from March till July. Its foliage is large, cordate, and pendulous; its flowers grow in umbels, and are nodding; its petals are white, and have purple tips resembling anthers; and its general appearance is superb and brilliant. It may be treated similarly to the orange-tree, but requires a richer soil. It constitutes a genus of itself, and is specifically called the African.

SPARROW. A large family of birds of the passerinous order. It is characterized by a strong conical bill, more or less thick at the base, and non-angular in the commissure. It comprises a considerable number of genera, including the sparrows proper, the weavers, the finches, the goldfinches, the linnets, the widows, the grosbeaks, and others. Most of the species feed more or less on grain, and are voracious and more or less destructive on the farm. See the article Hedge-Birds.

The common sparrow or house-sparrow, *Passer domesticus*, *Fringilla domestica*, or *Pyrgita domestica*, is one of the best known and most mischievous of the small birds of Britain. Its general plumage is brown, spotted with black above, and with grey underneath; its throat is black; its wing is marked with a whitish band; and the sides of the culotte of the male are red. It infests farm-steads and other inhabited places in great numbers, and is distinguished by greed and audacity. It builds under the eaves of tiles, in crevices or holes of walls, in the bore of old water pipes, and in any other small cavities which contain space enough for the hay and feathers which form the nest. Its egg is ten lines long and seven lines broad, and has a white ground colour spotted and streaked with ash-colour and dusky brown. The first batch of eggs in a season commonly consists of five or six; and often two other batches are laid; and no fewer than fifteen young birds are often raised in a year by one pair. The young are fed for a time with soft fruits, young vegetables, and various kinds of larvæ and insects. The full-grown birds are general devastators of both the farm and the garden; and, though believed by some naturalists to do quite as much good by destroying weeds and insects as harm by destroying crops and fruits, they are justly regarded by most gardeners and by nearly all observing farmers as pests of the same class with the most noxious vermin. Good methods of destroying sparrows, therefore, rank as usefully in practice as good methods of destroying rats and mice.

One effectual mode of diminishing their numbers is to catch them in a net at night when they roost by whole companies in ricks and stacks, or in a large trap net with a decoy bird. Many may be killed at a single shot by scattering corn in a long train, and firing at them while feeding. Count Buffon having been told that if sulphur were smoked under trees where the sparrows sleep at night, they would be suffocated and drop dead, he tried the experiment, but without success, though he took much pains and was interested in the issue, as he could not get them driven from the neighbourhood of his voleries. He placed on a wall covered with great Indian chestnuts, where the sparrows assembled every evening in great numbers, pots filled with sulphur, mixed with a little charcoal and rosin; and these substances being set on fire, caused a thick smoke, which had no other effect than to awaken the birds. As the volume ascended, they removed to the tops of the trees, and then retired to the neighbouring houses, but not one dropped. Another experimenter, imagining that the sparrows might readily be poisoned, mixed some arsenic with oatmeal, and strewed it in the paths between the beds of seedlings, which they were daily devouring, but they never touched the poison, and his experiment was as unsuccessful as that of Buffon's with the sulphur. Another gentleman, who had a large kitchen garden much infested with sparrows and chaffinches, was induced to go to considerable trouble and expense to prevent their ravages. He caused his labourers, when not otherwise employed, to prepare rods of wood about two inches broad, an inch and a half thick, and ten or twelve feet long, joining them together at the ends with similar rods, nine feet long, and, in the centre of the same, a similar rod to strengthen it. This frame is then wired with copper wire, close enough to prevent the birds getting through. The frame thus prepared is raised over the beds upon pieces of wood six inches long,—one piece at each corner of the

frame, and one in the centre. Wire is likewise passed around these pieces of wood to prevent the birds getting in at the sides. He says it is much cheaper than netting, and more sightly than matting. These wire-frames must prove effectual; but few would like the expense and trouble who could avoid it. "I am convinced from my own experience," says a practical writer, "that threads, with feathers or bits of paper tied along, and suspended so as to dangle over the beds, will prove effective in scaring both sparrows and chaffinches, which, with all their pert impudence, are exceedingly wary and fearful of danger. A coat and hat stuffed with straw so as to have some resemblance to a man, will not intimidate them so effectually as the thread and feathers. A neighbour of mine once set up such a man of straw in a cherry tree to scare the sparrows from the ripe cherries, among which they were making sad havoc; but, after the first day or two, when the novelty wore off, they alighted close to it, and devoured the cherries as before. Netting, in such cases, is the only effectual preventive; and unless threads and feathers, which I have not tried, might do, netting, or tying up the bunches in gauze or thin muslin bags, is the only way of protecting ripe grapes on the open walls, of which sparrows are very fond, and devour great quantities, always selecting the largest and the ripest, and sadly disfiguring the bunches. Should any person choose to try the thread and feathers, it ought to be fixed at some little distance from the fruit on the wall, so as to allow the feathers to move freely, as it appears to be their motion which intimidates the sparrows. White worsted threads, without feathers or paper, will scare them from pease or spinage, for a short time in spring, though they soon become familiar with this; but I have never found that they venture near when feathers or paper are used." In the farm-yard, or by the side of corn-fields, or in other situations where sparrows alight in large numbers, and make great depredations upon corn or vegetables, they may readily be thinned by various easy methods of poisoning, such as steeping some wheat in a decoction of nux vomica, and scattering it on or near the spots which they frequent.

SPARROW-WORT,—botanically *Passerina*. A genus of curious and ornamental, exotic, evergreen shrubs and undershrubs, of the wild olive family. Between a dozen and twenty species, all white-flowered, and varying in height from 6 inches to 3 or 4 feet, and principally blooming in May and June, have been introduced to the greenhouses of Britain, chiefly from the Cape of Good Hope; and they are propagated from cuttings, and for the most part love a soil of sandy peat. The allusion to a sparrow in both the popular and the botanical names is founded on the beaked form of the seeds. See the article CRYPTADENIA.—The name sparrow-wort is also given to a curious, white-flowered, thymeæous annual from the south of Europe,—*Stellera passerina;* and to a curious, white-flowered, globose-flowered, evergreen, shrubby heath from the Cape of Good Hope,—*Erica passerina.*

SPARTINA. A genus of grasses, of the subterminally spiked tribe.—The strict species, *Spartina stricta*, grows wild in the salt marshes of the coast of Britain. Its root is perennial, creeping, and strongly fibrous; its stems grow several together, and are from 10 to 20 inches high; its leaves are numerous, smooth, striated, and of a dull green colour; and its flowers bloom in August. The whole plant is hard, rigid, and tough, and popularly bears the name of cord-grass, and possesses economical adaptations similar to broom,—and hence the botanical name spartina.—The rushy species, *Spartina juncea*, is a native of North America, and was introduced nearly 70 years ago to Britain. It is perennial, and has a height of about 20 inches, and blooms in July and August, and ripens its seeds about the middle of September. It has been proposed as a cultivated field plant for yielding fibre; and it would produce well on poor silicious soils which are unfit for flax or for corn. Its manufactured fibre is clear and as strong and soft as that of flax, but is deficient in length. The plant, too, is of small value for forage. In the Woburn experiments, it was grown on a rich silicious sandy soil, and it yielded at the time of flowering 33,350 lbs. of green produce per acre,—of which only 1,433 lbs. consisted of nutritive matter.—Eight or nine other species, all perennial-rooted, but more curious than useful, have been introduced from North America, France, and Java.

SPARTIUM. See BROOM.

SPASMODIC COLIC. See COLIC.

SPATALANTHUS. A small genus of ornamental exotic plants, of the iris family. The name signifies 'delicate flower,' and is descriptive. The showy species, *S. speciosus*, is a native of the Cape of Good Hope, and was introduced to Britain in 1825. Its root is bulbous; its stem is about six inches high; and its flowers are red and very brilliant, and bloom from June till August. It loves a soil of sandy loam, and is propagated from offsets.

SPATALLA. A genus of ornamental, purple-flowered, Cape-of-Good-Hope, small, evergreen shrubs, of the protea family. Ten or twelve species, varying in height from 20 to 40 inches, have been introduced to Britain; and most require to be propagated from seeds.

SPATHODEA. A genus of ornamental, tropical, evergreen, ligneous plants, of the trumpet-flower family. Eight or nine species, varying in height from 6 to 25 feet,—some climbers, some erect shrubs, and some small trees,—have been introduced to the gardens and botanical collections of Britain; and they love a loamy soil, and are propagated from cuttings. The long-flowered species, *S. longiflora*,—called by Linnæus *Bignonia chelonoides*,—is a native of India, and

was introduced to Britain in 1816, and possesses high consideration in its native country. The juice of its leaves is given in mixture with lime juice as a remedy in maniacal cases; the infusion of its pleasant-tasted root is used as a cooling drink in fevers; and its beautiful, fragrant, purple-coloured or reddish flowers are woven into garlands, and presented at the shrines of the Hindoo idols.

SPATHOGLOTTIS. A recently discovered genus of ornamental, exotic plants, of the orchis order. Fortune's species, *S. Fortuni*, was introduced a few years ago to Britain from the granite mountains of Hong-Kong; and is a dwarf, terrestrial-rooting plant, of considerable beauty. Its bulb or corm lies dormant for some months after the foliage has decayed; its leaves are plaited, lance-shaped, and two in number, and grow up from the root-crown; and its stem rises by the side of the leaves, and attains a height of about a foot, and bears four or five pale yellow flowers,—the sepals and petals of which are ovate, the lip divided, the side lobes blotched with crimson, and the middle lobe cuneate.

SPAVIN. A threefold disease in horses. See the articles Blood-Spavin, Bog-Spavin, and Bone-Spavin.

SPAYING. The destroying of the ovaries of heifers, bitches, young sows, and other female animals, in order to prevent conception and to promote fattening. It is usually done by making an incision into the mid-flank on the left side with a lancet or sharp knife, cutting off the ovary, and stitching up the wound. The part should be so dressed as to exclude the air; and the animal should be kept warm and quiet for two or three days after the operation. The spaying of heifers is practised far less now than formerly,—not on account of any failure of its object, but because the great improvement in the breeds of cattle has correspondingly enhanced the value of breeding cows.

SPEARMINT,—botanically *Mentha viridis*. An indigenous, culinary, and medicinal herb, of the mint genus and labiate order. It grows wild in marshy places. Its root is perennial and creeping; its stem is quadrangular, leafy, erect, smooth, branching, and about two feet high; its leaves are opposite, nearly sessile, lanceolate, pointed, serrated, smooth, deep green above, pale and sometimes a little hairy below, about 2½ inches long and 1 inch broad; and its flowers grow in long, pointed, panicled spikes, on smooth partial footstalks, and have a smooth, tender, funnel-shaped, purple-coloured corolla, and bloom in August. This plant has a strong aromatic odour, and a warm and slightly bitter taste; and it retains these properties after being dried, and yields them to both alcohol and water. It acts as a stomachic and a carminative; and is used both in culinary preparations and in medicine. Its herbage is cut green for making sauces; its herbage is cut just as the flowers appear, to be dried for medicinal purposes; and the whole plant is cut when in full flower, to yield the essential oil of spearmint,—and this oil has a flavour similar to that of peppermint, and is used medicinally for the same purposes, but is less pungent and less grateful. An infusion of the dried herb is serviceable in allaying sickness and vomiting occasioned by weakness of the stomach. The plant is propagated in kitchen gardens by parting the roots in spring and autumn, by removing and transplanting young offset plants in March and April, and by cutting off the stalks in summer.

SPEARWORT. See Crowfoot.

SPECIES. There are several considerations which clearly establish the important fact that species have a real existence in Nature; that certain forms have been assigned to each animal from the origin of things; and that although the animals are liable to diverge from their primitive forms, they always possess a preservative tendency, a *nisus formativus*, and are ever ready to revert to the original type when the external causes of change are removed. The entire animal kingdom is divided into a number of distinct species, each of which perpetuates its own form, without ever transgressing certain limits, or acquiring the characters of another species.

In all the varieties observed to arise among the mammalia, the form of the bones preserves a remarkable stability, which would not always be expected from the appearance of the external parts. The Baron Cuvier compared the skulls of foxes from the North of Europe and from Egypt with those of France and with each other, yet he found no other differences than such as might distinguish one individual from another. The antlers of the rein-deer and stags often vary in size, and the same may happen with the tusks of the elephant; but two individuals of any one of these species, however dissimilar they may be in size, do not exhibit the slightest difference in the number of their teeth, or the articulations of their smallest bones. This is also observed with the domestic cattle, which may be destitute of horns, or have them of variable length, and yet they possess an exact correspondence in all the other parts of the skeleton. Thus the forms of the bones in general vary but little; while their modes of connexion, their articulations, and the form of the great molar teeth, remain constantly the same in each species. The divided hoof of the hog sometimes becomes consolidated, and this may be regarded as the extreme limit of variation among the bones of our domestic herbivorous animals. The variations of the bones in the different kinds of dog have undergone a special examination by M. Frederic Cuvier, performed at the request of his brother upon the specimens at the 'Museum d'Histoire Naturelle.' To enter fully into the details of this investigation would at present be out of place. It will suffice here to mention, that a general corre-

spondence in all the parts of their skeletons was found to exist, and at the same time some important variations, especially in the degree of elevation of the frontal sinuses. The teeth were always of the same number and general form; sometimes an additional false molar, or a tubercle, was observed on one side or on the other. It is well known that all dogs have five toes on the fore-feet, and only four on the hinder, while there is a slight trace of a rudimental fifth toe in the hinder metatarsal bone, which, however, shows no appearance on the outside. These toes being of unequal length, usually preserve the same relations in all the races; but sometimes a fifth toe exhibits itself on the internal surface of the hinder-feet. It is, however, generally very short and imperfect, and this last is the maximum of variation found in the skeletons of all the races of dogs. It thus appears abundantly evident, that animals now possess certain characters which remain permanent, and resist all modifications, whether arising from climate or domestication, or from a natural tendency to run into connate varieties.

Time, however, it has been said, may effect a perceptible modification in the entire characters of species. Fossil remains, and other geological monuments, appear to show that millions of years have elapsed since the first species of animals inhabited the earth, and it is asked, may they not have undergone many modifications during the interval? It is evident that we can only ascertain the effect which a very long time will produce, by comparing it with the change actually observed to have taken place during a shorter period. MM. Cuvier and Geoffroy-Saint-Hilaire sought out the most ancient documents which Egypt could afford, for the purpose of solving this question, so important to the naturalist, and essential to a knowledge of the past history of our globe. M. Cuvier examined with great care the ancient Egyptian obelisks transported to Rome, and found a perfect resemblance between the general form of the animals engraved thereon, and the common species of our own day. M. Geoffroy collected as many mummies of the lower animals and of man as he could find, and was led to form a similar conclusion. These monuments must have been from 2,000 to 3,000 years old. "For a long time," says M. Lacépède in the report he made upon these objects in common with MM. Cuvier and Lamarck,—"for a long time philosophers have been anxious to know whether species change their forms during the course of ages. This question, apparently trivial, is yet essential to the history of the globe, and to the solution of a thousand other questions not far removed from the gravest objects of human veneration. Never were we in a better condition to decide the question upon a great number of remarkable species, and for a long period of years. The superstition of the ancient Egyptians would almost seem to have been inspired by Nature, for the purpose of bequeathing to us a monument of her history. A people of fantastical opinions, by embalming with so much care the brute beings, objects of their stupid adoration, have left in their sacred grottoes complete cabinets of zoology. The climate has united with the art of embalming to preserve these bodies from all corruption, and we have now the means of ascertaining with our own eyes what was the condition of these animals 3,000 years ago. One can scarcely restrain the raptures of imagination upon seeing at the present day an animal preserved, with the smallest bone and hair perfectly distinguishable, which had 3,000 years since in Thebes or Memphis its priests and altars. But without wandering into all the subjects to which these associations give rise, we shall confine ourselves to noticing the simple fact—that these animals perfectly resemble those of the present day."

Although the bones of a species do not vary to any extent, yet the identity of osteological characters is not alone sufficient to establish an identity of species; and some species which possess a most exact similarity of structure are held, by the general consent of naturalists, to be of different species. It is almost impossible to distinguish the skeleton of the wolf from that of the wild dog of New Holland. Their teeth are the same; the vertebræ of the tail are equal in number; the feet have the same number of toes; and the bones of the head exhibit the same relations, except that the orbital fossæ are slightly larger in the wolf. The same thing occurs in the wolf of Canada, which is smaller than the common wolf, and larger than the dog of New Holland. The jackal also resembles the wolf-dog very closely, especially in the form of the head. There is likewise a most exact similarity in respect to the organs of sense among the New Holland dog, the Canadian wolf, and the jackal. Again, the quality and arrangement of the hair exhibit no essential differences, for they all may have either woolly or silky hair, according as they have been naturalized in cold or temperate countries. In fact, they only differ in colour. Yet all these genera merely vary from white to brown or black, and excepting the black wolf, which has the hair of a uniform colour, the others have hairs of fawn, black, or white so mingled together, that it is difficult to set down any colour as peculiar to either species, and which will not pass by insensible shades into another. What then, it may naturally be inquired, forms the distinction between a species and a mere variety; and how are we to ascertain those permanent characters which were assigned to our domestic animals at the origin of things? If these questions be considered in a purely abstract form, no difficulty can arise, as we have only to include in the same species all those animals, whose differences of external form and garb can be traced to some acknowledged causes of variation; while

the animals whose differences cannot be thus explained, must be held to belong to separate species. "Where two races of animals are distinguished by any undeviating marks in such a way that they never will, under any circumstances, pass into each other, or that the progeny of either can never acquire the characters of the other, they are of distinct species, and it matters not how wide or how narrow be the line of discrimination, provided that it never be broken in upon." But when we come to apply these abstract rules to the realities of Nature, we find that they are not always sufficient to distinguish the mere variety from the genuine species. The difficulty is further increased by the circumstance that many varieties or races of some species differ more decidedly among themselves, than the species of certain genera, where the objects are very numerous. Again, the greater part of our acquisitions are imported from remote and barbarous countries. "A large proportion," as Mr. Lyell observes, "have never even been seen alive by scientific enquirers. Instead of having specimens of the young, the adult, and the aged individuals of each sex, and possessing means of investigating the anatomical structure, the peculiar habits and instincts of each, what is usually the state of our information? A single specimen, perhaps, of a dried plant, or a stuffed bird or quadruped; a shell without the soft parts of the animal; an insect in one stage of its numerous transformations;—these are the scanty and imperfect data which the naturalist possesses. Such information may enable us to separate species which stand at a considerable distance from each other; but we have no right to expect any thing but difficulty and ambiguity, if we attempt from such imperfect opportunities to obtain distinctive marks for defining the characters of species which are closely related. When our data are so defective, the most acute naturalist must expect to be sometimes at fault, and, like a novice, to overlook essential points of difference, or pass unconsciously from one species to another."

Buffon established the criterion for the determination of species in the power of producing, by their union, races equally fertile with themselves, and this rule seemed to be confirmed by the experiments of John Hunter. They were of opinion, "that if a male and female produce an offspring which is prolific, the tribes to which the parents respectively belong are hence proved not to be specifically different, and whatever diversities may happen to characterize them, are in this case to be looked upon as examples of variation. But if the third animal be unprolific, it is to be concluded that the races from which it is descended are originally separate, or of distinct kinds. The fact that most hybrid animals are wholly unprolific, would appear to be a provision for the attainment of this desirable end, and for maintaining the order and variety of Nature. For if such had not been the condition of these intermediate animals, we have reason to believe that all the primitive distinctions would have been long ago totally effaced; a universal confusion of species must have ensued, and there would not be at this day one pure and unmixed species left in existence. The naturalists above mentioned, inferring, from the apparent utility of this law, that it must universally prevail, obtain by means of it a ready method of determining on identity and diversity of species." It is very clear that if two animals are prevented by any great disparity of organization or disposition from uniting, that the criterion of generation holds good to a certain extent. The bull and the goat, for example, would at once be pronounced to be distinct species. This rule may enable us to assert that two animals are not of the same species, but it does not always serve to discriminate between nearly-allied species. Hence it seems rather to be the first rude attempt at forming a criterion, than one which serves to mark out nice distinctions. The crosses among the dog, the wolf, and the jackal;—between the goat and the sheep;—the horse and the ass;—the lion and the tiger, with the occasional appearance of fertile hybrids in many, and the possibility of its occurrence in them all, show that the converse often fails. Although animals which do not generate together belong to distinct species, yet it is not true that distinct species must not generate together, nor does it follow that their progeny must always be sterile.

The determination of species by the property of producing fertile races, had previously been restricted by Frisch to such as generate together of their own accord, "von Natir mit einander gatten." Those artificial unions brought about by restraint, artifice, or domestication, were wholly excluded by him. But this restriction renders the rule useless in practice for determining those points where difficulties may chiefly be expected to arise. It is in respect to man and the domestic animals, or with animals brought from distant and uncivilized countries, that a rule is most required to distinguish the species from the mere variety. Blumenbach inquires, "When will it come to pass that all nearly-allied animals shall be brought together from remote countries, so as to submit them to the requisite experiments,—for example, whether the chimpansé, *Troglodytes niger*, from the Angola coast, will form a fertile race with the Orang outang, *Pithecus satyrus*, from Borneo?" This is a desideratum which the general establishment of zoological gardens alone can supply, but in the meantime we must seek some other criterion, which shall be applicable to man and the domesticated animals, for the determination of species. It is here that difficulties arise in drawing the line between the species and the variety. Tiliesius considers that several distinct species are confounded under the name of jackal or chacal, *Canis aureus*, while both Pallas and Gulden-

staedt regarded the jackal of Caucasus as the original source whence our domestic dogs are descended. Others again thought that the different kinds of dog have diverged fron the shepherd's dog, while some considered them all but as degenerations from the hyena, the wolf, or the fox. Thus it is precisely in those places where a fixed rule is most required that the breeding principle wholly fails, and we may seek in vain for any other. Blumenbach could propose none, but referred the determination of species to analogy and probability. "Fere desperem," he observes, "posse aliunde quam ex Analogia et verisimilitudine notionem speciei in Zoologiæ studio depromi." (I may almost despair of being able to derive the idea of species in the study of Zoology from any other source than analogy and probability.) Two races of animals which possess a general resemblance, and differ only in those respects which have been observed to vary, and can be traced to some well-known causes of variation, must at once be admitted to belong to the same species; but however near their general appearance may be, if they exhibit any difference which, in all our experience of the animal kingdom, has never been known to exist as a variety, they must be set down as distinct species. The proper determination of species rests, therefore, upon the knowledge of an immense number of facts, and forms one of the most difficult, as it is one of the most important, subjects to which the naturalist can direct his attention. Thus Blumenbach considers the ferret to be merely a variety of the polecat, *Mustela putorius*, not because they generate together, for perhaps the experiment may not yet have been made, but because the former is white with red eyes; and, from that well-known rule of analogy, that the same effects must be referred to the same causes, its origin is the same with those albino varieties produced daily among the domesticated mammalia. Again, the Indian elephant, *Elephas Indicus*, differs remarkably from that of Africa, *E. Africanus*, in the number and form of its molar teeth. Whether these animals will engender together it is perhaps difficult to determine; but on examining every specimen which reaches this country, the same difference is found to exist. Further, we know of no analogous instance of variety in the formation of the molar teeth among wild or domesticated animals. We, therefore, do not hesitate to set down these two elephants as distinct species.

There are other difficulties arising from the want of accurate information; and these, in the present state of the science, occur but too frequently. For example, the skin of an animal arrives from the Cape of Good Hope. At the first glance it appears, perhaps, to be a specimen of the common Cape otter, *Lutra capensis*, and this opinion may be further confirmed on examining the structure of its teeth. The colour of the breast and throat may seem of a purer white, and to be more extensive than usual, but this is a characteristic which might belong to a mere variety. On looking at the feet, we are much surprised at finding all the toes without nails, excepting on the second and third of the hinder-feet, where only a rude vestige of a nail can be observed. A carnassier without claws would seem an anomaly in creation. To suppose a being, compelled by its structure to live on animal food, and yet to be refused by Nature the weapons fitted for seizing its prey, disturbs our ideas of final causes, and we delight to trace order and regularity in the works of creation. The specimen must then be imperfect. It belongs to an old individual;—perhaps the claws may have dropped off through age or disease. We set it down, therefore, as a mere variety of the *Lutra capensis*. Some years afterwards, young individuals are brought with the nails entire; the first view then seems abundantly confirmed; perhaps even we applaud our own sagacity, and our extensive knowledge of final causes,—of those ends and uses for which the Creator designed the various parts of the animal world. Finally, another young individual is imported with all the characters of the original specimen, thus proving it not only to have been a distinct species, but entitling it to the rank of a separate genus—the *Aonyx*, or Nail-less otter of M. Lesson; and one more instance is afforded of the inexhaustible variety in the works of nature. When we find that even the possession of claws is not always indispensable to the subsistence of the carnassier, we may thence derive the salutary caution, not to confide too implicitly in analogical reasoning, if we wish to form correct views regarding new or unknown natural objects.

Since the supporters of the permanent characters of species thus find it difficult to fix any very definite rule for determining them, and as the characters themselves are seen to run into innumerable varieties, two very different theories have been proposed. Linnæus and Buffon asserted that only a small number of stocks were originally created, from which all the existing species have degenerated and diverged, from the influence of climate, food, and domestication, aided by a promiscuous intercourse, which has been limited only by their progeny ceasing to produce fertile races. On the other hand, Lamarck considered that the form of the body, and all the characters of species, were the consequence of the habits, the manner of living, and other circumstances, which have, in the course of time, given rise to the form of each species. Further, that man, and each higher animal, has originally risen from some lower division of the animal kingdom, by the gradual transition of the characters of one species into another, but always from the lower to the higher, with the transmission of such commuted characters to their posterity. These theories both agree in denying the fixed character of species. That of Linnæus

and Buffon would remove the character of durability from the species to fix it in some original stock, the type of the genus, the family, the tribe, or perhaps even of the order. That of Lamarck would overturn the permanent character of all forms. The first asserts the degeneration, the second the gradual development and perfectibility, of species. While the one reposes chiefly on the phenomena of variation, the other rests upon those general analogies among species, which have led Bonnet to form his universal chain of existence, and later writers their circular theories.

It is to Linnæus that we must assign the merit of relieving systematic botany from those accidental varieties which spring up daily in our gardens, and had been improperly raised by Tournefort and other former botanists to the rank of species. But the zeal of this great Naturalist in bringing down varieties from their undue elevation, led him to conjecture that many of those plants which had been discovered since the time of Tournefort might have been produced, during the intervening period, by the intermixture of species. From the impregnation of one kind of plant with the pollen of another, he was induced, not only to suspect that nature now produced new species by this means, but that, even at the origin of things, there had been created only a certain number of simple genera, the continual crossing of which has given rise to the immense number of species at present known. This hypothesis, which originated from the consideration of plants, was afterwards extended by Linnæus even to animals, and however plausible it may at first sight appear from contemplating those races, by which Nature has so infinitely varied some species in different parts of the globe, it seems, on a further consideration, to be wholly untenable. Contrivance and ingenuity, on the part of man, are always seen to be necessary to bring about the production of a hybrid or cross between two different species. There is further an impossibility of perpetuating these crosses as species or distinct races, arising either from their absolute or relative want of fecundity, or from that degeneration and deterioration to which their issue is subject. They always require the assistance of one of their primitive stocks, to prevent the new race from becoming wholly extinct. Further, in those genera and classes where the objects are very numerous, we often see two or more species formed evidently upon the same model, which may be more or less varied, yet they always remain distinct from each other. Examples of this are not wanting from the quadrumana and cheiroptera to the lowest species of zoophytes. We also see that those peculiarities which serve to characterize the several species, genera, or even natural families, continue to exist without there ever appearing before our eyes new links between allied species. For nearly two centuries, animals and plants have been observed with great care, yet there has not been one authenticated instance of a distinct and constant species, which has yet been proved to be of modern origin. Finally, those fossil shells and bones found in earthy strata, deposited during the earlier ages of animal life, exhibit the same variety, not only of those forms which are found at the present day, but also of many others now wholly extinct. These facts are opposed by a mere probability or conjecture, and we are hence compelled to consider species, although very nearly resembling each other, to have been so formed at the origin of things.

Buffon has carried these views regarding the degeneration of species among animals to a much greater extent than Linnæus did in respect to plants. After reducing the numerous races of domestic animals to certain original stocks, he grouped the allied species of quadrupeds into races or natural families. Assuming certain species to be the primitive stocks from which the numerous allied species at present existing have descended, he thence attempted to explain their degeneration, partly by their close affinities, but chiefly by those causes which are sufficient to vary the domestic animals. He thought that species, such as now are commonly admitted, did not formerly exist, and that we must seek for their characters in those natural groups which have served to form genera or families. The degeneration of species, according to Buffon, was one which preceded all history, and formed the most ancient of their changes. It appeared to arise in each family, or in each of those genera under which nearly-allied species are usually comprised. Only a few isolated kinds, he remarked, formed, like man, at once the species and the genus. The elephant, rhinoceros, hippopotamus, and camelopard, according to him, composed simple genera and species which were continued in a direct line, and without any collateral branches; while all the others appeared to form families, in which a chief and common stock might generally be observed, from which there seemed to proceed different offsets, increasing in number according as the individuals in each species were smaller and more fertile. Buffon on these principles reduced all the species of quadrupeds then known to thirty-eight families. He admits that this state of Nature has not come down to us, but is, on the contrary, the remnant of a former state of things, and that we can only acquire a knowledge of it "by inductions and relations nearly as fugitive as the time, which seems to have obliterated all traces of its existence."

Notwithstanding the opinion which M. F. Cuvier has hazarded upon this theory, "that it even now presents an appearance of the greatest probability," it is one to which we can by no means subscribe. After making due allowance for the influence of climate, food, and the numerous accidents to which all the individuals are

subject, these causes are wholly insufficient, however long we may suppose them to operate, to change the entire forms of animals, their proportions, and even their internal structure, to such a degree as this hypothesis would require. We see that those domestic animals which man has transported to the most opposite climates, have only changed the quality of their hair or their colour. The influence of pasture can only alter the height, the proportion of the horns, or perhaps add some lumps of fat to the body. But a small number of generations spent on another soil are sufficient to overturn whatever this race may have acquired during ages of cultivation. Again, if we consider those species, whether mammalia or birds, which are most populous in individuals, and at the same time the most fertile, the entire of their observed variations are by no means great. Some species which are very populous are nearly exempt from varieties, while others, though less fertile, vary much. Thus the common mouse and the mulot, *Mus sylvaticus*, are perhaps as populous as any species; yet their variations are rare;—and an infinite number of instances might be brought forward among the fishes and insects. There are even species very nearly allied to each other, and almost equally distributed in opposite climates, of which the one has run into a great number of varieties, while the others every where preserve a uniform resemblance to each other. The Polish marmot, *Arctomys bobac*, and the Siberian marmot, *Spermophilus citillus*, are striking instances that a vegetable diet does not give rise to greater varieties than animal food. The Polish marmot lives only on vegetables without ever touching animal substances, yet it remains unvaried, according to Pallas, from Poland to the banks of the Lena. On the contrary, the Siberian marmot, which is as carnivorous as the surmulot, *Mus decumanus*, has undergone many important variations of size, colour, and proportion in the same latitudes, and under similar circumstances.

Although the influence of DOMESTICATION [see that article] has a much more powerful tendency to occasion variation, than all those reverses and changes which the wild species can experience, yet man has not succeeded in altering the nature of any one of these animals, so as to form a new, distinct, and permanent species. The horse and the ass, in their transitions from the wild to the domesticated state, have undergone less variation than some other wild species, which climate alone has been sufficient to modify. The Bactrian camel and the dromedary retain their natural forms in the few countries where they are naturalized. Buffon considered the humps of the camel to have been occasioned by the long habit of carrying burdens; but the wild camels of Thibet and China have the same humps and callosities as their domesticated brethren. Pallas has correctly observed, that he might as well have regarded the follicule of the musk, and the dorsal gland of the peccari, as abscesses arising from disease. The ass is more harshly treated than the camel, the alpacas are as much accustomed to carry burdens, yet they are without humps. The horse and the ass have not acquired callosities on those places where they have so long been exposed to the friction of the saddle and harness.

Climate and food, however long we may suppose these causes to operate, are wholly unable to account for the existence of the numerous species of animals which cover the face of the globe. We see that the preservation of the races among our domestic animals, and the improvement of the breeds, depend chiefly upon the peculiarities of the individuals selected to propagate. Graziers have long since laid down those rules by which the domestic animals, and especially the horse, can be rendered larger, more beautiful, or more vigorous than they would have been if left uncultivated. But it is only by continued care that the purity of the breeds can be preserved, and they ever exhibit an inclination to resume the characters of the wild animals. We thus see that the tendency of the offspring to retain the characteristics of its parent is powerful enough to counteract all those causes which may modify the external forms of animals. Thus the introduction of rams of a good breed corrects the fleeces of the worst flocks in a single generation, and even in the least favourable climates. The Angora goat has imparted his silky fleece to the Swedish flocks, and they maintain this character for several generations. In Russia also, the stallions with a frizzled and crisp hair, impart to their foals a similar coat and of the same colour. The wild, as well as domestic animals, also tend continually to maintain their primitive forms in opposition to all the influences of climate and food, which are wholly insufficient to induce this supposed degeneration and degradation of species. Whenever some accidental connate deformity or partial excrescence becomes hereditary, as sometimes happens, the natural liberty of intercourse soon re-establishes the original form; and it is only by interfering with their unions that we can succeed in rendering permanent the accidental varieties of our domestic animals. In the wild state also, the females are led instinctively to prefer the most courageous of the males, the most perfect, and the most masculine of their species. The males, likewise, instinctively prefer the most beautiful of the females; and thus they both tend to transmit to their offspring the most perfect form of their species. See the article BREEDING.

Since Nature then has placed an instinctive mutual aversion in animals of different species, —since she has rendered hybrids either sterile or weak and imperfect,—if allied animals distributed in remote parts of the globe are found to be incapable of yielding fertile races, we have presumptive evidence that this supposed degen-

eration of species cannot have existed, and we derive from the known insufficiency of the present causes of change a positive ground for inferring their descent from distinct original types. The mere circumstance of our being able to induce by art and contrivance a fertile union between two species, is not sufficient to counteract this evidence, when we see that these same species preserve themselves distinct in the wild state, and continually maintain certain well-defined peculiarities. Pallas was led to infer that some of our domestic animals, such as the sheep, the goat, and the dog, are factitious beings, not proceeding from any permanent origin, but from the union of several distinct species, such as the dog from the wolf, the fox, and jackal; the sheep from the mouflon and Siberian argali; and the common goat from the Persian and Caucasian goats with the ibex. We know that these animals have given rise to fertile hybrids; and hence it becomes impossible to say how far their varieties may be owing to foreign contamination, or to the occurrence of connate varieties in the original species. It is, however, useless to indulge in conjecture where data are defective; but from analogy we might infer that a very small part of their varieties have been owing to foreign admixture.

It now remains for us to notice the theory of the successive transition of species proposed by M. Lamarck. According to him, the habits and manners of life assigned to each animal do not follow from any original form peculiar to its species; but that, on the contrary, the form of each species is the result of its habits, its manner of life, and other influential causes, which, in the course of time, have constituted the shape of the body and the parts of the animal. With new forms, new faculties have been acquired; and thus gradually Nature has produced the animals as we now see them. We must in justice remark, that this theory has been censured in this country with undue severity, from its appearing at first sight to dispense with the agency of a First Cause in the creation of the several species of animals. But in reality, a creative power is as indispensable in *maintaining* the successive transition of forms, as in originally *creating* them. Lamarck himself was well aware of this, for he observes, "When I see that Nature has placed the source of all the actions of animals, of all their faculties, from the most simple to those which constitute instinct, industry, and finally reasoning—in their *wants*, which alone establish and direct their *habits;* ought I not to acknowledge in this power of Nature, that is to say, in the existing order of things, the execution of the will of its Sublime Author, who has imparted them the power?" As an illustration of this supposed transition of species, we shall show M. Lamarck's method of explaining upon his theory, how it comes to pass that some mammalia can fly. A very ancient race of common squirrels had long amused themselves with leaping from tree to tree, and thence had acquired a habit of extending their limbs like a parachute. From frequent repetitions of this act, the skin of their sides became gradually enlarged, in course of time, and a loose membrane extending from the fore to the hind feet, embraced a large volume of air, and broke the force of their fall. In a word, they acquired the characters of the flying squirrels, —*Pteromys*. These animals, however, were still without membranes between their fingers. But a race of squirrels of much higher antiquity, after undergoing the preceding metamorphosis, had acquired a habit of taking still longer leaps than the former. Accordingly the skin of their sides became more ample, uniting not only the fore and hind legs, but even the tail with the hinder feet, as well as the fingers with each other. These now form our flying lemurs,—*Galeopithecus*. There was, however, a third race of squirrels vastly more ancient than any of these, which had contracted a habit, in the course of time, of extending not only their limbs, but also their fingers. From this habit, long preserved and become inveterate, they not only acquired lateral members, but an extraordinary elongation of the fingers of the anterior limbs, with large intermediate membranes, so that at length they constituted those singular wings which we find in the bats,—*Vespertilio*. "So great is the power of habit," observes Mr. Lamarck, "that it singularly affects even the conformation of the corporeal parts, that it imparts to those animals which have contracted certain habits through a long course of ages, certain faculties which other animals of different habits do not enjoy."

Upon this theory, it was requisite that the higher orders of animals should be regarded as of the greatest antiquity, a longer time being necessary for their transition from those simple forms, which were supposed to have been first created. "I have no doubt," proceeds Lamarck, "that all the mammalia have originally sprung from the ocean, and that the latter is the true cradle of the whole animal kingdom. In fact, we still see that the least perfect animals are not only the most numerous, but that they either live solely in the water, or in those very moist places, where Nature has performed, and continues to perform, under favourable circumstances, her direct or spontaneous generations; and there, in the first place, she gives rise to the most simple animalcules, from which have proceeded all the animal creation."—(Philosophie Zoologique, tom. 2, p. 456). We must remark, that there has never yet been, within the historical era, a well authenticated fact of any animal of one species having acquired organs or faculties belonging to another; nor are any species known to have lost any of their senses or powers to make way for new ones. It must further be observed that, while we have never found any of these transitions in circumstances within the sphere of our

investigations, Lamarck places them precisely in those, where they cannot be proved or disproved by direct observation. Where did these transitions begin? In the abysses of the ocean, where man has never penetrated, and where myriads of beings lie concealed from his observation, perhaps for ever. What animals owe their origin to spontaneous generation? Animalcules, a class of beings the most remote from our observation, and whose forms can only be traced through the deceptive medium of the microscope. When did these transitions occur? Before the historical era, in those remote and inaccessible ages, whose existence is alone attested by the organic remains imbedded within the surface of the earth. But, observes Lamarck, "there is a very good reason why we do not see those changes successively performed, which have diversified the known animals, and brought them to their present state. We see them only when they are finished, and not when undergoing the change; and we very naturally infer that they always have remained as we see them." This is a prejudice. "If the average duration in the life of each generation of men were only a second, and if there be a pendulum mounted and in motion, each generation would consider this pendulum really to be at rest, never having seen it change in the course of their lives. The observations of thirty generations would not demonstrate any thing positive concerning the vibrations of this instrument."

We may remark, that our sole means of judging of unknown objects is by comparing them with others which are known, and that it is unphilosophical to found a theory of what occurs, or has occurred, in remote and inaccessible parts of the creation, in direct opposition to what is seen to happen within our own sphere of observation. The earth appears to be at rest, if it be compared with objects on its surface; and we reason correctly, for, *in respect to them*, it is at rest. But on referring it to the solar system, we at once perceive it to be in motion. Again, if we compare the entire solar system with the more remote heavenly bodies, analogy would lead us to expect that our system may be in motion towards the fixed stars, and that these stars themselves may only be fixed, relative to our own limited means of observation. To suppose the fixed stars to be really motionless, would be as great a violation of analogical reasoning, as those theories inflict which deny the permanent characters of species. All the sciences adopt this mode of reasoning when the contemplated object is inaccessible to direct experiment or observation. On looking abroad into Nature, the chemist finds every thing in a state of composition. He nowhere discovers pure oxygen, chlorine, calcium, or potassium, because nearly all the unions which simple substances were capable of forming spontaneously have already occurred. The naturalist is disposed to imagine that something similar to this may have taken place among the species of animals and plants; but the chemist analyzes the compounds of these substances himself, and he sees their combinations going on before his eyes. The naturalist cannot bring forward one single instance of the degeneration or transition of species from one form to another. The weak point of the Lamarckian doctrine, in the absence of positive proof, is a violation of one of the first rules of analogy. Mr. Lyell correctly remarks, in his recent criticism on this subject, that "no positive fact is cited to exemplify the substitution of some *entirely new* sense, faculty, or organ, in the room of some other rendered useless. All the instances adduced go only to prove, that the dimensions and strength of members, and the perfection of certain attributes, may, in a long course of generations, be lessened and enfeebled by disuse; or, on the contrary, be matured and augmented by active exertion, just as we know that the power of scent is feeble in the greyhound, while its swiftness of pace and its acuteness of sight are remarkable;—that the harrier and staghound, on the contrary, are comparatively slow in their movements, but excel in the sense of smelling. It is evident, that if some well authenticated facts could have been adduced to establish one complete step in the progress of transformation, such as the appearance in individuals descended from a common stock, of a sense or organ entirely new, and a complete disappearance of some other enjoyed by their progenitors, that time alone might then be supposed sufficient to bring about any amount of metamorphosis. The gratuitous assumption, therefore, of a point so vital to the theory of transmutation, was unpardonable on the part of its advocate."

We have now seen that some mammalia are capable of undergoing a very considerable variation, not only in their instincts and intelligence, but also in their external forms; that the variations which each individual can be made to undergo by the circumstances in which it is placed are but very rarely transmitted to posterity, while connate modifications usually end in becoming hereditary;—and that there are certain limits beyond which no species has been observed to vary, so that we are fully entitled to conclude, that a certain form was assigned to each species at the origin of things.

If it be true that the numerous varieties of the cow, the horse, the dog, and other domestic mammalia, are the effects of the slow and continued influence of certain causes, which in the first instance, induce a departure from the primitive type in the evolution of connate varieties, and afterwards transmit these variations to posterity, giving rise to their several distinct races; —it ought to follow, that in all these artificial beings, whose characters man has for a time rendered permanent, there should be a continual tendency, when left to their own resources, to

assume the form of the original type. On allowing the domestic animals to run wild,—on permitting them to substitute the wandering habits and precarious subsistence of mountains and forests for the uniform and regular diet of the stable, we ought to find that their acquired characters disappear, that all the individuals bear that marked resemblance to each other, which will serve to indicate both the identity of their species, and the original form from which the races have diverged. The experiments confirming the truth of this conclusion have long been performed on the largest scale in the immense continent of America. It is well known that the Europeans, on the first discovery of the New World, sought in vain for any vestige of that animal creation to which they had so long been familiarized. Those useful animals, without whose aid, in the first instance, the civilization of man might have been indefinitely retarded, had to be transported to America to supply the immediate necessities of the earlier colonists. Soon, however, the accidental flight of some animals to the woods, hastened probably by the abundant supply of food, and a favourable climate, which, in increasing their fecundity, rendered a vigilant care of them superfluous, a large proportion became absolutely wild, and the establishment of wild individuals in the immediate neighbourhood of the tame herds, soon exerted a direct modifying influence over the latter. Hence, in America, we may see performed, on a magnificent scale, the converse of that gradual modification which the domestic animals underwent in their original transition from the wild state; and may further compare those half domesticated herds, acknowledging only a partial submission to man, with the humble individuals of their own species, which still yield him a patient and implicit obedience.

It is evident that careful observations should be multiplied over the whole continent of America, in order to render this investigation complete; but we owe to M. Roulin the merit of having traced some changes in a portion of this vast country. That learned physician, during his residence in Colombia for six years, has collected a number of interesting facts which were communicated to the Royal Academy of Science at Paris in the year 1828. These observations were made in New Grenada and a part of Venezuela, from the 3d to the 10th degree of north latitude, and from the 70th to the 80th degree of west longitude. However limited this tract of country may appear, it offered unusual facilities for observation, being traversed throughout its entire course by the great cordilleras of the Andes, which are here divided into three principal chains; so that, within the distance of a few leagues, the same living animals were investigated, though resident in one district, where the medium temperature is only 50° Fahrenheit, and in another where it varies from 77° to 86°. The mammalia transported from Europe to America were the hog, the horse, the ass, the sheep, the goat, the cow, the dog, and the cat. It becomes important to ascertain whether these animals retain the forms acquired in Europe, or whether they have undergone any considerable change. By carefully comparing these phenomena with the circumstances under which they have arisen, much light may be thrown upon those modifications which probably attended the transition of these animals from the wild to the domestic state.

The first hogs brought to America were introduced by Columbus, and became established at Saint Domingo in November 1493, being the year which followed its discovery. During the following years they were successively carried into all those places where the Spaniards attempted to fix themselves, and, in the period of about half a century, they might be found wild from the 25th degree of north to the 40th of south latitude. In no place do their important changes appear to have been effected by climate, and they have reproduced everywhere with the same facility as in Europe. Most of the pork consumed in New Grenada comes from the warmest valleys, where the hogs are bred in large numbers, from their maintenance costing but little. During some seasons they are even supported wholly by wild fruits, and especially by those of the several species of palms. From roaming constantly in the woods, the hog has lost in this district all traces of his former domestication. His ears are straight and erect, his head has widened and become elevated in the upper region. The colour has again become constant, being entirely black. The young pigs have several fawn-coloured stripes, like the European wild boar in its youth, and upon a ground of the same colour. Such are the hogs brought to Bogota from the valleys of Tocayma, Cunday, and Melgar. Their hair is scanty, and on this account they bear a striking resemblance to the wild boar of Europe, from a year to eighteen months old. This deficiency of hair is not, however, peculiar to the hogs of Grenada, but is also experienced by the common wild boar of Europe. M. Roulin observed an instance of it in France, at a farm near Fougères, where seven or eight of these animals were brought up together. One of them, being about two years old, had been fed in a stable from the beginning of spring, with the intention of fattening it for the market. Though the animal had not been closely confined in this place, the good feeding of the stable was sufficient to induce it to remain at home. Its hair had almost wholly fallen off from the effects of the heat, and it exhibited a most perfect resemblance to the hogs of Melgar above described, except that the two horizontal stripes on the sides of the muzzle were more decidedly marked, and gave it a stronger expression of ferocity. The hogs of the Paramos, which are mountains at least 8,200 feet above the level of the sea, approach much more

nearly in appearance to the wild boar of the European forests, from the thickness of their hair, which has even become frizzled. Beneath, in some individuals, it has been observed to assume a woolly appearance. The hog of these elevated regions is, however, small and stunted, from the want of sufficient food, and the continued action of an excessive cold. In some sultry districts, the hog is not black, like those above described, but red, like the peccari, during its youth. At Melgar, and in the other places above mentioned, instances have been known where the hogs are not entirely black ; but these are comparatively rare. There is a variety called *cinchados*, or ' girthed,' because they have a large white band underneath, which usually unites on the back, and always preserves a uniform breadth ; and the young individuals of this variety bear the same stripes as those of the pure black breed. The only hogs in Colombia which resemble the common pigs of Europe, have been imported within the last twenty-five years, and these do not come direct from Europe, but from the United States of America ; and it must be recollected that in the neighbourhood of New York, where this race has long been domesticated, it experienced the influence of a climate very nearly the same as our own.

The horse has become wild in several districts of Colombia, especially in the plains of San Martin, among the sources of the Meta, the Rio Negro, and the Umadea, where small troops of chestnut horses may be observed. Their limited numbers, the narrow range to which they are confined, and the immediate neighbourhood of the inhabited districts, have prevented them from acquiring those peculiarities which Azara has related of the wild horses of Paraguay. They go about in small squadrons, composed of an old horse, five or six mares, with some foals, and one squadron is completely isolated from another. Instead of approaching the caravans to entice the domestic horses, they run away on the first appearance of a man, and do not stop their flight until he is out of sight. Their movements are graceful, especially those of the leader, but their forms, though not heavy, are wanting in elegance. In the Hatos des Llanos, the horses are almost wholly left to themselves. The herds are assembled together at intervals to prevent them from becoming absolutely wild, to extract the larvæ of the gad-fly, and to mark the foals with a red-hot iron. From this independent kind of life, they begin to acquire the uniform colour of the savage races. The chestnut bay is not merely the prevalent colour, but it is very nearly the only one. Something similar to this has probably happened in Spain with the wild horses (*cavallos cerreros*) which wander in the mountains ; for in the Spanish proverbs, the horse is often noticed by the name of *el bayo* (the bay), as well as the ass by the term *rucio* (grey). In the small Hatos which are found on the plateau of the Cordilleras, the effects of domestication are more perceptible. The colours of the horses become more various ; there is also a greater difference in their height ; and while many are more diminutive than the average of the species, only a few surpass the medium size. As long as they live continually in the fields, their hair is tolerably thick and long, but a few months' residence in the stable is sufficient to render it short and glossy. It is customary to cross this breed of horses with the races from the warm valleys, especially with those of Cauca. On some properties where this precaution has not been attended to, the horses have become perceptibly smaller, though the pastures have long been celebrated for their richness. The hair has grown to such a degree as to render their appearance absolutely deformed. In respect to the useful qualities, this breed has lost but little ; and the horses belonging to one canton are even celebrated for their swiftness. When a horse is brought from the Llanos de San Martin, or from Casanare, to the plateau of Bogota, he must be kept in the stable until he is accustomed to the climate. If allowed to run loose at once into the fields, he grows thin, contracts a cutaneous disease, and often dies in a few months. The pace which is commonly preferred in the saddle-horses is the amble ; this they are made to acquire early, and the greatest care is taken not to allow them, when mounted, to take any other pace. In a short time, the limbs of these horses usually become stiff ; and then, if otherwise of a good form, they are allowed to run in the Hatos as stallions. From them a race has descended, in which the amble is with the adults the natural pace. These horses are called *aguilillas ;* and they form a remarkable instance of the transmission of acquired habits from the parent to his offspring.

The ass has undergone very few alterations in its form or habits in all the provinces visited by M. Roulin. At Bogota it is very common, being there used for transporting building materials ; but being badly taken care of, and exposed to the inclemencies of the weather, without receiving sufficient nourishment, the race has become small and pitiful. It is covered with very long and uncombed hair. Deformed individuals are often seen, not only among the adults, which are loaded prematurely, and before they have acquired sufficient strength, but also among the foals at their birth. Perhaps the latter circumstance may arise from the ill treatment of the dams during the period of gestation. In the low and warm provinces this animal is less neglected, as it is required for the production of mules. Being well fed, at least in these districts, it becomes larger and stronger ; its hair also is shorter and more polished. In no province, however, has the ass reverted to its wild state.

The sheep was originally transported to the New World from Spain ; and the earliest importation

appears not to have been the Merino variety, but another, which the Spaniards call *de lana burda y basta* (with wool coarse and rude). It is very common on the Cordilleras, at an elevation of 3,300 to 8,200 feet. In no place do the sheep appear to have escaped from the protection of man, and hence we find that their manners have undergone scarcely any change; nor can any alteration in their forms be observed, except a slight diminution of stature. Within the limits above defined, the sheep propagate readily, and almost without requiring any care; but the reverse happens in the hotter districts. It appears that in the plains of Meta it is very difficult to rear lambs; and no sheep are to be seen from the river to the foot of the Cordilleras, although their skin is very much in demand to make a kind of parchment, and that its price is as high as the hide of an ox. In the valley which separates the most eastern chain from the central, they may perhaps be sometimes seen, but always in small numbers. The females are not very fruitful, and the lambs are difficult to rear. There is one very curious phenomenon exhibited by the sheep of this district. The fleece grows upon the lambs in the same manner as in most temperate climates, provided they are sheared as soon as it has arrived at a certain degree of thickness, in which case the wool grows again, and continues to observe the same order. But if the favourable period for stripping the animal of its fleece be allowed to pass, the wool thickens and becomes matted together, it detaches itself in flakes, and finally leaves behind —not, as we might expect, a growing fleece, or a naked and diseased skin—but, a short, glossy, and compact hair, exactly resembling that of the common goat in the same climate.

Although the goat is evidently best fitted for a mountainous region, it seems to thrive better in the low and sultry valleys than in the more elevated regions of the Cordilleras. In the former districts it multiplies rapidly, generally bearing two young at a birth, often three, but never six, as some have been pleased to assert. Its height is diminutive, but in other respects its form has greatly improved. Its body is more slender, the shape of its head is more elegant, more pleasingly disposed, and usually less overloaded with horns. The agility of this animal, and its taste for climbing and leaping, are also singularly increased. In the public square of a village, M. Roulin has often seen them leaping more than four feet upwards to the mouldings on the pilasters of the church. The projecting place on which their feet rested was not three square inches; yet in this position, so difficult to preserve, they remained for hours together, without any other apparent object than that of warming themselves in the direct solar rays, as well as in those reflected from below. These goats are covered with short hair, very glossy and thick; and although they may be seen to possess all the shades of colour, yet the most common is fawn, with a brown stripe on the back, and black symmetrical marks upon the face. The she-goats of Europe strikingly exhibit the influence of domestication in causing a great enlargement of the udders; for this acquired character has entirely disappeared in the she-goats of America.

The establishment of the larger cattle in America must be dated, like that of the hogs, from the second voyage of Columbus to St. Domingo. In the latter place they multiplied rapidly, and the island soon became the nursery from which these animals were transferred to different points on the coast of the mainland, and thence to the interior of the continent. Although these numerous exportations must have diminished their numbers considerably, yet we are informed by Oviedo, that within twenty-seven years from the discovery of St. Domingo, herds of 4,000 head of cattle might frequently be encountered, and that there were even some containing at least 8,000. In the year 1587, the number of hides exported from this island alone amounted to 35,444, while 64,340 appear to have issued from the ports of New Spain. This was the sixty-fifth year after the capture of Mexico, before which event the Spaniards were entirely occupied in warfare, and it strikingly evinces the extreme rapidity with which these animals will increase their numbers when placed under favourable circumstances. While the cattle were in small numbers, and grouped around the habitations of their masters, they succeeded equally well almost everywhere; but as soon as their numbers became greatly increased, it was discovered that in certain districts they could not exist without the assistance of man. Unless they were able to find a certain quantity of salt, either in the substance of the plants which formed their food, or in the streams which in some districts acquire a brackish taste from the saline particles contained in the soil, it was found to be absolutely necessary to furnish it to them directly. If this precaution were not attended to, they became stunted and poor; many of the females ceased to be fruitful, and the herds rapidly disappeared. Even in those districts where the cattle can exist without this assistance, it has been found advantageous to distribute salt at stated intervals to the herd. This is one principal means of attaching them to a particular spot; and so great is the avidity with which they take this substance, after being for some time deprived of it, that when it has been distributed to them two or three times at the same place, they are seen running from all quarters to the spot as soon as they hear the horns which the herdsmen sound before making the distribution. If, however, the country yields a sufficient supply of salt, and if the herdsmen neglect to assemble the cattle from time to time, they become in a very few years wholly wild.

This has happened at two places to M. Roulin's knowledge, the one in the province of San Martin, in a property belonging to the Jesuits, at the time when this religious order was expelled, the other in the province of Mariquita at Paramo de Santa Isabel, in consequence of the abandonment of some works where the natives washed for gold. In the latter place, the cattle have not remained in the districts where they were originally placed, but have mounted the heights of the Cordilleras to seek the region of the grasses, and there live in a temperature almost uniform of 48° to 50° Fahrenheit. To this spot the peasants of the villages Mendez, Piedras, and some others situate in the plains, sometimes come to hunt them. They drive with knotted cords small divisions of the herd towards the places where snares have been previously prepared. Whenever they obtain possession of one of these animals, it is often impossible to conduct it alive from among the mountains. This does not arise from the resistance which the captive makes, for after a little time its violence begins to diminish; but when the animal begins to perceive the futility of its efforts to escape, it is often seized with so great a tremor over the whole body, that it falls to the ground; to make it rise becomes impossible, and it dies in a few hours. The want of salt to preserve the meat, the distance from any inhabited district, and the difficult nature of the roads, prevent the hunters from deriving any other advantage from the slain animal than the portion which they can consume upon the spot. These disadvantages render the hunting of wild cattle by no means frequent; and the hunters always run the risk of being surprised by the snow, which often falls in these elevated regions. When the snow lasts many days, these unfortunate men, accustomed to the continual warmth of the adjoining valleys, are sure to perish. If, however, they are so fortunate as to bring one of these animals from the mountains, it is not difficult to tame; this is effected by confining it near to the farm, by supplying it regularly with salt, and habituating it to the sight of men. M. Roulin never had an opportunity of seeing one of these animals alive, but he tasted the flesh of a wild calf which had been killed on the evening of his arrival. Its flavour did not in any respect differ from that of the common domestic calf; the hide was remarkably thick, in other respects of the usual size; the hair was long, thick, and rough. In the province of San Martin he, however, saw a wild bull of a chestnut colour, pasturing in the Llanos in the midst of the domestic cattle. The wild bulls pass the morning in the woods which cover the base of the Cordilleras, and do not appear in the Savannah until about two hours after noon, when they come out to feed. As soon as they perceive a man, they hasten to regain the forest at a full gallop. The hide of the wild bull does not appear to differ in any respect from that of the domestic cattle which inhabit the same districts. In both they are much heavier than the hides of the cattle brought up on the plateau of Bogota, and the latter yield in this respect, as well as in respect to the thickness of their hair, to the wild cattle of Paramo de Santa Isabel. In the warmest parts of the provinces of Mariquita and Neyba, there are some herds of horned cattle with their hair extremely scanty and fine; they are given, by antiphrasis, the epithet of *Pelones*. This variety is transmitted to their descendants, but no care is taken to preserve the breed, as the Pelones are unable to bear the cold of the elevated regions of the Cordilleras, where the cattle intended for consumption or exportation must remain for some time to fatten. There is also another variety of cattle in this district called *Calungos*, having the skin entirely naked like the Barbary dog. As these animals are more feeble and delicate, it is usual to kill them before they are old enough for breeding. These never appear in the cold districts.

In Europe, where the milk of the cow forms a very important article of rural economy, it is usual to milk her continually from the moment of the birth of her first calf until she ceases to be fertile. This practice, continually repeated upon all these animals for a long series of generations, has had the effect of producing permanent alterations in the species. The udders have acquired an extraordinary size, and the milk continues to be secreted even after the calf has been removed. In Columbia, however, the introduction of a new rural system, the abundance of cattle in proportion to the number of inhabitants, their dispersion in pastures of very great extent, and a number of other circumstances which need not here be detailed, have counteracted this effect of domestication. The organization and function of the udder soon resume their original state when freed from the long-continued influence of habit. At present if a cow of Columbia be intended to yield milk for the dairy, the first care must be to preserve the calf; it is allowed to remain along with its mother for the entire day, during which she is permitted to suckle it. They can be separated only at night, and the milk secreted during the interval of their separation alone becomes available for economical purposes, and accordingly it is abstracted every morning. If the calf happen to die, the secretion of the milk is immediately stopped.

SPECKLINIA. A genus of ornamental, tropical, epiphytous plants, of the orchis order. It comprises a number of species which have been commonly but mistakenly assigned to the genus dendrobium.

SPECULARIA. A genus of ornamental, hardy, annual plants, of the bellflower family. It was recently constituted out of the genus prismatocarpus, just as that was constituted out of the genus campanula; and it takes for its type

the well-known Venus's looking-glass, called by Linnæus *Campanula speculum*.

SPEED. Inflammatory fever in cattle. See the article Inflammatory Fever.

SPEEDWELL,—botanically *Veronica*. A large genus of ornamental plants, of the figwort order. Eighteen species grow wild in Britain; about 120 species have been introduced from other countries; and about 50 more are known. Some have perennial roots and terminal clusters; some have perennial roots and lateral clusters; and some have annual roots and solitary axillary flowers. A small number are greenhouse evergreen undershrubs; a small number are greenhouse evergreen herbs; about twenty are hardy annuals; and nearly all the rest are hardy, annual-stemmed, herbaceous perennials. A few have a height of from 4 to 8 feet,—and a few have a height of only from 1 to 4 inches; but the great majority have a height of from 10 inches to 3 feet. A few have white flowers; a considerable number have flowers of some shade of pink or red; and nearly all the rest have blue flowers. Most of the perennials are decidedly beautiful, and of very easy culture; and they thrive in any common garden soil, and are, for the most part, readily propagated by division of the plant.

Two of the indigenous species are noticed in the articles Beccabunga and Bird's Eye.—The officinal species, *Veronica officinalis*, inhabits dry sandy banks, barren heaths, mountain pastures, poor woods, and waste grounds. Its root is perennial; its stems are cylindrical, prostrate, creeping, variable, and from 6 to 18 inches long; its leaves are elliptical, roundish, obtuse, and serrated; and its flowers grow in lateral clusters, and have a light blue colour with dark streaks, and bloom from April till July. The leaves of this plant have sometimes been used as a substitute for tea.—The spiked species, *V. spicata*, is a perennial-rooted indigen of the chalky pastures of England, and has a height of about a foot, and carries blue flowers from July till September.—The hybrid species, *V. hybrida*, is a perennial-rooted indigen of the mountains of some parts of England, and has a height of from 10 to 15 inches, and carries blue flowers from July till September.—The mountain species, *V. montana*, is a perennial-rooted inhabitant of the moist woods of Britain, and has a height of 6 or 8 inches, and carries blue flowers in July and August.—The bristled species, *V. setigera*, is a perennial-rooted indigen of the meadows of some parts of Scotland, and has a height of 3 or 4 inches, and carries blue flowers from April till July.—The saucer-leaved species, *V. scutellata*, is a perennial-rooted indigen of the marshes of Britain, and has a height of about 2 feet, and carries flesh-coloured flowers from June till August.—The pimpernel-like species, *V. anagallis*, is also a perennial-rooted indigen of the marshes of Britain, and has a height of about 2 feet, and carries blue flowers in July.—The shrub-like species, *V. fruticulosa*, is a perennial-rooted indigen of some of the lofty mountains of Scotland, and has a shrubby stem and a height of 6 or 8 inches, and carries flesh-coloured flowers from June till August.—The rock species, *V. saxatilis*, is also a perennial-rooted indigen of some of the lofty mountains of Scotland, and has a small, low, prostrate stem, and carries blue flowers in July.—The serpyllium-leaved species, *V. serpyllifolia*, is a small, prostrate-stemmed, perennial-rooted indigen of the meadows and pastures of Britain, and carries blue flowers from April till June. Five or six varieties of it have been introduced from Continental Europe.—The obtuse-leaved variety of the alpine species, *V. alpina obtusifolia*, is a perennial-rooted native of the Scottish mountains, and is small and creeping, and carries blue flowers in May. Five varieties of this species, and also the normal plant, have been introduced from Continental Europe.—The field or rural species, *V. agrestis*, is a small, creeping, annual weed of the cultivated lands of Britain, and carries blue flowers from March till July. Two varieties of it, the opaque and the various-coloured, also occur in our fields.—The corn-field species, *V. arvensis*, is a small creeping weed of old walls and other situations in Britain, and carries blue flowers from April till July.—The spring and the three-leaved species, *V. verna*, and *V. triphyllos*, are small, annual weeds of the sandy fields of Britain, and carry blue flowers in April and May.—The ivy-leaved species, *V. hederæfolia*, is a small, creeping, annual weed of the cultivated lands of Britain, and carries blue flowers from March till June.

SPELT. See Wheat.

SPERGULA. See Spurrey.

SPERMACETI. A fatty substance prepared from a peculiar secretion of the cachelots or spermaceti whales. These animals are occasionally seen in the European seas, but chiefly inhabit the Southern Ocean. They are of a blackish colour in the upper part of the body, and white on the belly; and each, when full grown, measures on the average about thirty feet in girth at the thickest part of the head, and about sixty feet in length. Their head is very voluminous, and has proportionally a far greater size than the body; the upper jaw has no whalebone and either no tooth or a very small and unprojecting one; the under jaw is narrow, elongated, and armed on each side with a range of conical or cylindrical teeth, which, when the mouth closes, are sheathed in cavities of the upper jaw; the cranium or brain-depository is situated in the posterior part of the head, and is rather small; and large cavities, separated and covered by cartilages, and filled with a spongy oily mass, which becomes fixed as it cools, occupy most of the superior part of the enormous head, and send off oil-filled ducts in ramifications through several parts of the body and through the blubber. The common spermaceti oil of commerce, similar

in appearance and properties to common whale oil, but of finer quality, is obtained from the spongy oily mass of the cavities, by digging it out and dripping it; and spermaceti itself, by first powerfully compressing the mass, next purifying the solid hard product by boiling in water, next subjecting it three times to the washing action of a weak ley of potash, and next concreting it in cooling vessels. Purified spermaceti commonly occurs in flaky or crystalline plates of a white colour and silvery lustre; it is brittle, and feels soft and slightly unctuous to the touch; it has no taste, and scarcely any odour; it is insoluble in water, but dissolves in about thirteen times its own weight of boiling alcohol; and it liquefies at a temperature a little below 212° Fahrenheit, and evaporates, a very little altered, at a temperature of 500°. It saponifies with pure potash, and then generates an acid to which Chevreul gave the name of cetic acid. Spermaceti is used by pharmacists in the compounding of several ointments, and sometimes by physicians as a demulcent and an emollient.

SPERMACOCE. See Buttonweed.

SPHAGNUM. A genus of mosses, of the gynostomous tribe. Four species, all of a yellowish green colour, grow in the bogs of Britain at all seasons of the year; and one of these, the blunt-leaved, comprising the three varieties, common, smaller, and floating, is one of the most abundant and most generally diffused of our bog mosses. See the article Bog.

SPHENOGYNE. A genus of exotic, ornamental, yellow-flowered plants, of the sunflower division of the composite order. About a dozen species, varying in height from 6 to 20 inches, four of them annuals, and the rest evergreen undershrubs, and the greater number very handsome, have been introduced to the gardens of Britain, principally from the Cape of Good Hope; and the ligneous kinds love a soil of loam and peat, and are propagated from cuttings.

SPICKNEL,—botanically *Athamanta*. A genus of plants, principally herbaceous and white-flowered, of the umbelliferous order. Upwards of a dozen species, varying in height from 1 foot to 5 feet, have been introduced to Britain from Siberia, Continental Europe, and the Levant; and all thrive in any common garden soil, and are propagated from seeds.

SPIDER. The aranea genus or araneides family, or spinner group, of the pulmonarious order of arachnides. See the articles Insects and Red Spider.

SPIDERWORT,—botanically *Tradescantia*. A genus of ornamental exotic plants, of the commelina family. Several hardy annuals and biennials, several hardy annual-stemmed herbaceous perennials, and upwards of a dozen tropical evergreen herbaceous species, have been introduced to the gardens of Britain; and most love a soil of rich mould, and have a height of from 10 to 30 inches, and carry blue flowers in the latter part of summer. The Virginian species, *Tradescantia Virginica*, one of the hardy perennials, was the earliest introduced, and is the best known, and may serve as a sufficient specimen of the whole. "The root," says Miller, "is composed of several fleshy fibres, which spread wide on the ground, from which arise many long, narrow keeled leaves, which embrace each other at their base. They are about half an inch broad at the bottom, and gradually lessen to a point; they are veined and rough on their edges, of a greyish colour and succulent. Between the leaves arises a thick jointed stalk about a foot long, garnished at each joint with one leaf, whose base embraces it. At the top of the stalk are two leaves which spread asunder; above these come out many flowers almost in a sort of umbel; these have a three-leaved empalement, and three large roundish petals of a deep blue colour, which in the morning spread open flat, but in the middle of the day they shrink up, and do not open again. But there is a succession of flowers from the same bunch daily, for a considerable time. The germen swells to a roundish capsule with three angles, having three cells, including a few angular seeds. It flowers in June, and there is commonly a succession of flowers for two months on the same plant, especially in cool moist seasons." Five varieties of it occur in gardens,—the double-flowered, the pilose, the white, the red, and the blue and white.

SPIGELIA. A genus of exotic herbaceous plants, of the gentian family. The Maryland species or worm-grass, *S. marilandica*, is a medicinal plant, and has a place in all the British pharmacopœias. It is a native of the warmer parts of North America, and was introduced to the gardens of Britain towards the close of the 17th century. Its root is perennial; its stems are annual, simple, erect, quadrangular, rough, rigid, and about 6 or 8 inches high; its leaves are opposite, sessile, ovate-lanceolate, entire, smooth, and spreading; and its flowers grow in solitary spikes, and have a bright red colour without, and a deep orange within, and bloom in July and August. The root is the medicinal part, and is most active in a recent state. It has a bitter taste; and acts as a narcotic, an anthelmintic, and a purgative; and is administered either in substance or in the form of aqueous infusion.

SPIKED-ROLLER. See Roller.

SPIKENARD (Ploughman's). See Baccharis.

SPIKE-RUSH, — botanically *Eleocharis*. A genus of rush-plants, of the cyperaceous order. Three species grow wild in Britain; seven or eight have been introduced from North America, Australia, and Continental Europe; and about twenty more are known. They are principally bog plants, more curious than either beautiful or useful; and all the species in British collections are perennials of between 3 and 15 inches in height. The three indigenous species are *E.*

palustris, *E. multicaulis*, and *E. acicularis*; and all bloom in July.

SPILANTHES. A genus of tropical herbaceous plants, of the sunflower division of the composite order. Seven or eight annual species, principally yellow-flowered and from 6 to 18 inches high, have been introduced to Britain; and one of these, *S. oleracea*, is used in India as a culinary plant, and is known there under the name of the cress of Para. It is perfectly hardy, and ripens its seeds in the open air at Paris.

SPINACH, — botanically *Spinacia*. A small genus of herbaceous plants, of the goosefoot family. The common pot herb species, *Spinacia oleracea*, is the well known culinary spinach, cultivated in kitchen gardens for sake of its large succulent leaves. It is of uncertain origin, but is known to have been cultivated in Britain since soon after the middle of the 16th century. It is an annual, and comprises two very distinct varieties, the prickly and the smooth. Its stems are hollow and branching, and rise to the height of about 18 or 24 inches; the leaves of the prickly variety are triangular and shaped like the point of an arrow, and those of the smooth variety are round and more succulent; the male flowers come out in long spikes, and are apetalous and of a herbaceous colour, and shed a profusion of yellowish pollen; and the female flowers grow on separate plants, and sit in clusters close to the stem at every joint, and are small, herbaceous, and apetalous, and comprise each a roundish compressed germen, which afterwards turns, in the prickly variety, to roundish seeds armed with short acute spines, and in the smooth variety to smooth seeds. Some subvarieties of the prickly kinds occur, with different size and shape of leaves, and with different degrees of prickliness in the seeds. The smooth variety is more impatient of cold than the prickly variety, and is raised for spring and summer crops, and loves a rich, moist, mouldy loam, in an open situation; and the prickly variety is raised for autumn and winter crops, and loves a light, dry, moderately fertile soil, in an open situation in the warmer season of the year, and in a sheltered border in the colder season. The ground, in every case, ought to be well dug and very thoroughly pulverized. Sowings of the smooth variety may be made every week or fortnight or month from the beginning of February till the end of summer, either broadcast or in drills nine or twelve inches apart; and sowings of the prickly variety may be made for a main crop in the early part of August, and in successions for about a month, either broadcast or in shallow drills six or twelve inches apart. The seed should be sown thin, the broadcast sowings regularly raked, and the drill sowings thinned and weeded.

SPINACH (New Zealand). See New Zealand Spinach.

SPINACH (Wild). See Goosefoot.

SPINDLE-TREE,—botanically *Euonymus*. A genus of ornamental shrubs and small trees, of the staff-tree tribe. One species, the European, grows wild in the hedges of Britain, and at the same time is a favourite plant in shrubberies and pleasure grounds; about twenty species have been introduced from North America, Austria, Caucasus, India, Nepaul, China, and Japan; and at least ten more are known. One or two of the introduced species are hardy evergreens; several are frame or greenhouse evergreens; and the rest are hardy deciduous shrubs. These plants have inconspicuous flowers, and carry them in axillary bunches; but most have very distinct and beautiful foliage, and make a pleasing figure in shape, habit, and general appearance.

The European spindle-tree, *Euonymus europæus*, is a deciduous shrub, or low tree, not often found much above 12 feet in height, but sometimes, in favourable situations, reaching even to 30 feet, and upwards. It has smooth branches, and opposite, lanceolate-ovate leaves, very minutely serrated, or saw-edged. The flowers are small, greenish white, somewhat star-shaped, produced from the axils of the leaves, and usually borne about three together on one peduncle or stalk; and they bloom in May; and are succeeded by handsome rose-coloured fruit, which ripen in September. It is found plentifully in Britain, and throughout the middle and north of Europe. There are four varieties of this species, *E. e. foliis variegatis*, which has sickly-looking variegated leaves; *E. e. latifolius*, with broader leaves than the normal plant; *E. e. nanus*, a dwarf growing variety, altogether smaller; and *E. e. fructu-albo*, which produces white instead of rose-coloured berries.

The broad-leaved spindle-tree, *Euonymus latifolius*, is a deciduous shrub, or low tree, of excellent habit, with smooth branches, large broadly-ovate leaves, and axillary-branched peduncles of small greenish white flowers, which are produced in June and July, and are succeeded by handsome scarlet fruit. It grows 10 or 12 feet high, sometimes more; and is one of the very handsomest of the genus, though, from being generally treated only as a small shrub, it is seldom to be found assuming its naturally interesting character. It is a native of Europe, and particularly of the south of Germany, and of France and Switzerland.

The warted-branched spindle-tree, *Euonymus verrucosus*, is a deciduous shrub, of rather a limited growth, seldom exceeding 10 feet, and assuming a conical outline, with warted branches, and ovate, serrated leaves. The flowers are borne about three on a peduncle, and have a greenish brown colour, and bloom in May and June. It is a native of Europe, particularly of Austria, Hungary, and Carniola.

The dark purple flowered spindle-tree, *Euonymus atropurpureus*, is a deciduous shrub of limited growth, introduced from North America, where

it was found on the banks of rivulets, from New York to Carolina. The branches are smooth; the leaves lanceolate, and serrated; the flowers small, dark purple, numerously produced on the peduncles from opposite sides of the stem, and appear in June and July, and are succeeded by red fruit.

The American spindle-tree, *Euonymus americanus*, forms a sub-evergreen small shrub, growing from 6 to 8 feet in height. The leaves are elliptic-lanceolate, and serrated; the branches smooth; the flowers small, yellow tinged with red, from one to three on a peduncle, produced in June and July; and they are succeeded by scarlet fruit which hang like those of the strawberry tree, and have a very gay appearance, and which occasion the tree to be called, in America, the burning bush. It is found in damp and shady places, in hedges, among rock, and on the borders of streams, in North America, extending from New England to Carolina.

The narrow-leaved spindle-tree, *Euonymus angustifolius*, is a small deciduous shrub, growing 5 or 6 feet high, with smooth branches, and leaves generally linear-elliptical, or oblong-elliptical. The flowers are small, usually solitary, of a yellowish red, as in *E. americanus*, to which plant it is nearly allied. It is found in shady woods, in Georgia, North America. It flowers in June.

Hamilton's spindle-tree, *Euonymus Hamiltonianus*, is a shrub or low tree, attaining 20 feet in height, and remarkable for the whiteness of its stem, and the large size of its leaves. It is scarcely hardy, having been killed to the ground by the winter of 1837–8, but sprang up again hardy, with vigour. It has an erect trunk and spreading branches, forming a dense fastigiate bush with numerous suckers. The branches are smooth; the leaves are lanceolate, and finely serrated; the flowers, yellowish green, in forked bunches, or cymes.

The obovate-leaved spindle-tree, *Euonymus obovatus*, is a trailing shrub, extending over a considerable circumference, but not often exceeding a foot in height. The stem is decumbent and rooting, producing upright angled shoots; the leaves are broadly obovate, obtuse, and finely serrated; the flowers, three in a bunch, and pinkish, and are produced in June and July. It inhabits marshy places in Pennsylvania.

The large flowered spindle-tree, *Euonymus grandiflorus*, is a deciduous shrub, growing from 8 to 10 feet high, with smooth branches, obovate-oblong serrated leaves, and large white flowers, in June, succeeded by pendulous clusters of yellow fruit. It inhabits the forests of Nepaul.

The Japan spindle-tree, *Euonymus japonicus*, is a handsome evergreen shrub, nearly hardy, having been but little injured by the winter of 1837–8, when planted against a wall, and standing out in ordinary winters with very little protection. It has obovate, dark green shining leaves, and whitish or pinky flowers, which are produced in July. The plant is not usually, in this country, of very large growth; but in Japan, where it is a native, it grows 20 feet and upwards. There is a variety called *E. j. foliis variegatis*, which differs in having variegated leaves; and has been found to be more hardy than the normal plant.

These plants are usually increased either by seeds, which are produced abundantly, by cuttings, or layers, which root freely, or by grafting or inarching, in the case of newly-introduced or rare kinds. Seeds and cuttings, however, are the most usual modes of propagation; and in raising plants in this way, nothing is required beyond the ordinary method of carrying this operation into practice. Some of the species, as *E. europæus* and *E. verrucosus*, are best suited for the company of large and common shrubs,—where, however, if not planted too closely with the other trees, they will individually attain considerable size, and become rather interesting than otherwise. All the commoner deciduous European species grow very freely in the ordinary soil of gardens, without the least difficulty. The North American species are more difficult to cultivate; they appear to grow naturally in damp shady woods, and on the margins of streams, and hence require more moisture and shade than are usually afforded them in this country. Some are even found in marshes, and would consequently require the characteristic features of the native localities to be imitated in artificial cultivation. These appear, also, to prefer a soil rather sandy or peaty; and hence, perhaps, the kinds of soil and situations usually provided for rhododendrons, and similar plants, would be found most suitable for these. The kinds which succeed best under this mode of treatment, are *E. americanus*, *E. atropurpureus*, *E. angustifolius*, and *E. obovatus*. The Nepaul, or Indian species, and *E. japonicus* and its variety, the most desirable plants of the family, inhabit, for the most part, mountains of considerable elevation, and require, in their artificial management, to be provided with a soil as little subject to superabounding dampness as can be provided. Situations, however, which are usually devoted to the growth even of common shrubs, are generally sufficiently drained to secure all that these plants require. *E. japonicus*, and its variegated variety, are suitable plants both to plant out as specimen bushes on a grass plat, in sheltered situations, and to plant against walls or buildings which it may be desirable to cover with a perennial foliage.

SPINE. The backbone or vertebral chain of a vertebrated animal. It commences with the bone which supports the head; and is continued in the bones of the neck, the back, and the loins; and, in most species, is prolonged beyond the posterior members, in the small bones of a tail. Its vertebræ work upon one another in sockets,

and are perforated by a canal or prolonged annular opening in which is lodged the spinal marrow or great nervous medullary cord. The combination of strength and mobility, of bone and muscle, of circulatory vessels and nervous processes, of earthy matter and cartilage and flesh and fluid, of the most diversified and mighty functional powers in the structure of the spine, viewed both in itself and in its connexions with the entire organization of the body, constitute a perfect museum of wonders, and afford multitudinous and overwhelming displays of the wisdom and goodness of the Creator, and present a brilliant field of study to at once the anatomist, the physiologist, the moralist, and the physico-theologian. Fracture of the horse's spine sometimes occurs in leaping a ditch, in struggling during a painful operation, or on other occasions of sudden and severe contortion; and it is always fatal.

SPINE. A sharp, indurated, terminating point in the leaf or calyx of a plant. It is well exemplified in the piercing armature of the thistles. Some spines are mere processes from the angles or apexes of leaves; and others, as in the common furze, may be regarded as comprising the whole bulk and substance of the leaves. Prickles and thorns differ from spines in their constituting an armature of the stems and branches of plants; and prickles issue merely from the bark, and are stripped off along with it, while thorns issue from the wood, and occur only on ligneous plants, and may be regarded as abortive and indurated buds.

SPIRÆA. A genus of ornamental plants, of the rosaceous order. Three species grow wild in Britain; and upwards of forty have been introduced from other countries, principally North America, Siberia, and Eastern Europe. A few are hardy, perennial-rooted herbs, propagable by division of the plant; and all the rest are hardy deciduous shrubs, varying in height from 1½ to 8 feet, and propagable in some instances from layers, and in others from suckers. A few have red or pink flowers; and nearly all the rest have white flowers. Two of the indigenous species are noticed in the articles Meadow-Sweet and Dropwort; and one of the introduced species, in the article Goats'-Beard.

The willow-leaved species, or common spiræa, or spiræa frutex, *S. salicifolia*, occurs wild in some of the woods of Britain, but has been introduced, in several varieties, from Russia and Tartary, and ranks as an ornamental plant in gardens and pleasure-grounds. It is a deciduous shrub, of commonly about 5 or 6 feet in height. The root is spreading, and sends up a profusion of stems and suckers. The old stems are branching; and the suckers of a single season's growth are as high in autumn as any of the stems. The bark of all is smooth; that of the old stems is red, though for the most part clouded with a dusky matter; that of the shoots from the stems is lighter yet reddish; and that of the suckers from the root is white. The leaves grow without order on the branches, and have a fine green colour, and are spear-shaped, obtuse, naked, and serrated. The earliest flowers are produced in June, at the ends of the branches which grow from the main stem; and before these cease to bloom, flower buds appear at the ends of the suckers, and are generally larger and fairer than those of the stems, and often keep up a succession of bloom till late in autumn. The flowers are produced in double branching-spikes, which are broadest toward the base, and diminish gradually upward, and end obtusely at the top; and they are of a pink or pale red colour; and, though individually small, yet, in consequence of being aggregated in these thick spikes of 4 or 5 inches in length, they have a good appearance. Five varieties of this species occur in collections,—the white, the alpine, and the broad-leaved, all with white flowers,—the large-flowered, with pink flowers,—and the flesh-coloured, with carmine flowers.

The tomentose or downy spiræa, *S. tomentosa*, is a native of North America, and was introduced to Britain in 1736. It is a deciduous shrub of about 5 feet in height. Its stems possess a considerable degree of downiness; its branches are covered with a purple bark; its leaves grow irregularly on the branches, and are ovate-lanceolate, unequally serrated, fine green above, and downy below; and its flowers grow in double branching spikes at the ends of the branches, and have a bright pink or red colour, and bloom from July till September, and make a fine appearance.

The hypericum-leaved spiræa, or hypericum frutex, *S. hypericifolia*, is a native of Canada, and was introduced to Britain in 1640. It is a deciduous shrub of five or six feet in height; and it has great beauty and elegance,—not so much from its natural form of growth, or from the colour of the bark or leaves, as from the flowers; for the branches are produced irregularly. The older shoots are covered with a dark brown bark; the younger shoots are smooth and lighter, and are tinged with red. The leaves are small, though of a pleasing dark green colour, and they come out irregularly and are entire. The flowers are produced in May, almost the whole length of the branches, and are of a white colour; and though separately small, they are collected in umbels which sit close to the branches, and ornament their whole length, so that scarcely anything but flowers, and the main stalks, are to be seen. The shrub, in fact, has the appearance of one continued flower, branched out into as many different divisions as there are twigs,—every twig looking at a little distance like a long narrow spike of flowers; and these being all over the shrub and of a pure white, they make a delightful show.

The sorbus-leaved spiræa, *S. sorbifolia*, is a na-

tive of Siberia, and was introduced to Britain in 1759. It is a deciduous shrub of 3 or 4 feet in height. Its young branches are clothed with a purplish bark; its leaves are beautifully pinnated, and closely resemble those of the service-tree; its folioles are oblong and uniformly serrated, and generally amount to about four pairs on each leaf, and are exceedingly ornamental; and its flowers grow in panicles at the ends of the branches, and are white, and bloom in August. A variety called the alpine, *S. s. alpina*, is comparatively dwarfish.

The opulus-leaved spiræa, or Virginian guelder rose, *S. opulifolia*, is a native of North America, and was introduced to Britain in 1690. It is a deciduous shrub of 7 or 8 feet in height. The branches are covered with a dark brown bark, which peels off in winter, and discovers an inner, which is smooth and of a lighter colour; so that in winter this shrub has a very ragged look. The leaves resemble those of the common currant bush, which has occasioned its being called by some the currant-leaved guelder rose; they are for the most part lobed like them,—though all are not alike, some being divided into more than three lobes, whilst others are scarcely divided at all; and they are serrated and of a palish green colour, and stand irregularly on the branches, on long green footstalks. The flowers are produced in June, at the ends of the branches; they are white at their first opening, and afterwards receive a reddish tinge, which is still heightened before they die off; and though each is rather small, and stands on a separate footstalk, many of them grow together in large umbels; and they are succeeded by bunches of reddish, cornered fruit, which make a pretty show in autumn. A variety occurs called the small woolly,—*S. a. tomentella*; and this is propagated from suckers,—the normal plant from layers.

The crenated-leaved spiræa, *S. crenata*, is a native of Podolia, and was introduced to Britain in 1739. It is a deciduous shrub of from 2 to 4 feet in height. Its branches come out irregularly, and are covered with a dark brown bark; its leaves are small, serrated, and of a pleasant green colour; and its flowers grow in roundish bunches on the sides of the branches, and are so profuse and plentiful as to cover almost all the branched part of the shrub, and have a white colour, and bloom in April and May, and make a handsome appearance.

Some of the most interesting of the remaining species are the germander-leaved, *S. chamædrifolia*, 20 inches high, white-flowered, blooming in June and July, introduced in 1789 from Siberia, and comprising four or five varieties from Germany, Hungary, and Canada; the elm-leaved, *S. ulmifolia*, 3 feet high, white-flowered, blooming in June and July, introduced in 1790 from Carniola, and comprising a variety called the leafy; the pretty, *S. bella*, 2 feet high, red-flowered, blooming in July and August, and introduced in 1820 from Nepaul; the meadow-rue-like, *S. thalictroides*, 2 feet high, white-flowered, blooming from May till July, and introduced in 1816 from Dahuria; the smooth-leaved, *S. lævigata*, 4 or 5 feet high, red-flowered, blooming from April till June, and introduced in 1774 from Siberia; and the three-lobed, *S. trilobata*, 3 or 4 feet high, white-flowered, blooming in May, and introduced in 1801 from Siberia.

SPIRALEPIS. A genus of ornamental, Cape-of-Good-Hope plants, of the thistle division of the composite order. Four species, varying in height from 6 to 15 inches, all evergreens, classed by the old botanists with the genus gnaphalium, and severally carrying flowers of red, brown, purple, and purple and green, have been introduced to the greenhouses of Britain; and all love a mixed soil of sand and peat and loam, and may be treated in the manner of the other greenhouse "everlastings."

SPIRANTHES. See Ladies' Traces.

SPIRIT. See Alcohol.

SPIRIT-LEVEL. See Levelling.

SPIT DUNG. See Farm-Yard Manure.

SPLEEN. A spongy, honey-comb-like organ, comprising numerous little cells and multitudes of minute vessels, and lying along the left side of the stomach of some of the higher orders of animals. It is one of the few organs whose precise functions have as yet baffled scientific research; but has been supposed to serve as a reservoir for any excess of fluid which the stomach receives and does not immediately require for any purpose of digestion. It is sometimes very much enlarged, and has even been known to be ruptured; but does not appear to be often or seriously the seat of disease.

SPLEENWORT. See Asplenium.

SPLENT, or Splint. A bony excrescence on the inside of the shank-bone of the horse. It seldom occasions lameness unless when so situated as to interrupt the motion of the knee-joint, or to interfere with the back sinew or suspensory ligament of the leg. In all ordinary cases, it may be let alone, or merely bathed with camphorated spirit or with spirit and vinegar; or even when it occasions slight lameness, it may generally be sufficiently cured or controlled by being for some time kept constantly moist with camphorated spirit or with spirit and vinegar through a swathing of soft linen; and only when it causes serious lameness or becomes very unsightly needs it be attacked with any appliance intended to remove it. The old barbarous practices of bruising a splent with a hammer, chopping it off with a mallet, cutting it off with a saw, boring it with a gimlet, sweating it down with hot oils, and slitting down the skin and the periosteum over it, are never necessary and ought to be avoided and abhorred. The strongest measure requisite for the removal of almost any bad recent splent is to shave off the hair, rub in a little strong mercurial ointment for two days, and afterwards

apply a blister, and perhaps also a second blister. But a new, ingenious, generally successful, and but slightly painful method of reducing splents has been introduced by Professor Sewell. "He removes any inflammation about the part by the use of poultices or fomentations; and then, the horse being cast, the operation is commenced by pinching up the skin, immediately above the bony enlargement, with the finger and thumb of the left hand, and with the knife, or lancet, or scissors, making an orifice sufficient to introduce a probe-pointed bistoury, with the edge on the convex side. This is passed under the skin along the whole length of the ossification beneath, cutting through the thickened periosteum down to the bone; and this being effectually completed by drawing the knife backwards and forwards several times, a small tape or seton is inserted, and if the tumour is of long standing, kept in during a few days. Perhaps slight inflammation may appear, which subsides in a few days if fomentation is used. The inflammation being removed, the enlargement considerably subsides, and in many cases becomes quite absorbed."

SPONDIAS. See Hog Plum.

SPONGE. A genus of coralliferous polypi. They are marine fibrous bodies, whose only sensible portion seems to be a kind of tenuous gelatine, which dries off when the bodies are removed from their habitat, and which leaves scarcely a trace of itself, and no trace whatever of any moving part or strictly true animal organism. A tremulousness or contraction is said to occur in living sponges when they are touched, and a kind of palpitation also is said to be observable in the pores or orifices of their surface; but the reality or at least the sentiency of these alleged motions is rather questionable. Sponges assume exceedingly different shapes, each according to its species, and present resemblances to shrubs, vases, fans, horns, tubes, globes, and other objects. The common or officinal sponge, called by scientific naturalists, *Spongia officinalis*, is familiar to almost every person. In its natural or living state, it is a flexile, fixed, torpid, polymorphous animal, comprising innumerable reticulate fibres or small mutually interwoven spires, clothed with a thin gelatinous flesh, full of small mouths, by which it absorbs and ejects water; and in its dead state, it remains nearly the same as before except for being freed from its functional gelatine,—but may be described as a brown mass of extremely fine, flexible, elastic fibres, perforated with numerous intercommunicating pores and little irregular canals. It is found principally in the Mediterranean and the Red Sea; and occurs on rocks and stones at considerable depths beneath the surface; and is obtained in large quantities by divers belonging to the islands of the Grecian Archipelago; and has long been imported to Britain in large quantities from Smyrna. In a well cleaned state, it is of great service in the practice of surgery, and in many of the cleaning operations of the stable, the farmery, the bath, and the bedroom,—being soft, light, and very porous, rapidly absorbing by capillary attraction either water or any other liquid in which it is immersed, and as readily parting with it by compression. When digested in boiling distilled water, it yields a considerable proportion of gelatine, and loses much of its flexibility, and becomes capable of crumbling when dry; when boiled with potash, it saponifies; and when burnt, it yields iodine and perhaps bromine. Its principal constituents are gelatine and albumen, with a small portion of common salt and some carbonate of lime. It is, of course, too expensive to be generally or normally used for manure; and when in any case it becomes available for that purpose, it needs first to be reduced in texture and considerably decomposed.

SPONGE-TREE,—botanically *Acacia Farnesiana*. A small, ornamental, fragrant, evergreen, tropical tree, of the mimosa division of leguminosæ. It was introduced to the hothouses of Britain from St. Domingo about the middle of the 17th century. Its stem rises to the height of about 15 feet; its leaves are bipinnate; its prickles are stipular and straight; and its flowers grow in globose heads, and have a yellow colour, and bloom from June till August.

SPONGIOLES. The pulpy and bibulous extremities of the fine fibres or extreme radicles of the roots of plants. They comprise each one or more central ducts or vessels, enveloped by a cellular tissue; but they have no epidermis or cuticle, and are supposed to consist of the nascent or newly-formed tissue of the root. They occur only at the extremities of radical fibres, and are constantly advancing or changing place with the growth of the radicles. They absorb the food of plants from the soil, and constitute the mouths of the radicles pushing onward in search of it, and take it in only in a liquid condition, and probably exert in some degree both an electric and a chemical power over the materials of it in the action of absorbing them, yet not to such an amount as to prevent them from being seriously controlled in their secretions, and even absolutely poisoned, by peculiar conditions of the soil. See the article Absorption in Plants.

SPOONBILL,—scientifically *Platalea*. A genus of birds, of the cultirostrous family of waders. Their general structure is near akin to that of the storks; but their bill, whence they derive their name, is long, flat, broad throughout, widened and flattened at the end so as to form a spatula-like disk, and has two shallow grooves extending from the base almost to the end, but without being parallel to the edges.—The white spoonbill, *Platalea leucorodia*, is an occasional visitant of the British shores, and one of the most singular-looking birds ever seen in our country. Its total length from the point of the bill to the tip of the tail is about 32 inches,—and the portion of this in the bill alone is about 9 inches; its en-

tire plumage, except a band of buff feathers at the bottom of the neck in front, is white; its occiput is surmounted by a crest or plume; and its bill, legs, toes, and claws are black. It feeds in a very similar way to storks, herons, and bitterns; and it occurs throughout the eastern continent, and builds there on high trees.

SPORADIC DISEASES. Diseases which occur only in particular subjects, or affect only particular constitutions or ages. Strangles, for example, is a sporadic disease of young horses; and distemper is a sporadic disease of young dogs. Sporadic diseases are contradistinguished, on the one hand, from specific diseases which attack only certain species or genera of animals, and, on the other, from epidemics and endemics which attack individuals of all ages and constitutions; and they form a very extensive class of diseases.

SPORE, or SPORULE. A microscopic, reproductive granule in cryptogamic plants, analogous in nature and function to the seed of a phænogamous plant. The spores of minute cryptogams, and even those of some of the comparatively large musci and fungi, are produced in prodigious numbers, and multiply with amazing rapidity; and being at the same time so light and minute as to float on every breeze and mingle invisibly with the common air, they become everywhere diffused throughout the atmosphere, and are always ready to sit down and grow wherever they can find a suitable nidus. The globules or pouches in which those of many species are contained, and which bear the name of sporidia, are themselves quite or almost microscopic; and yet a single sporidium of a dust fungus, such as that of smut, has been calculated to contain no fewer than ten millions of spores. See the articles ACOTYLEDONOUS PLANTS, CELLULARES, CRYPTOGAMOUS PLANTS, FUNGI, MILDEW, SMUT, and MOULD.

SPORIDIUM. See SPORE.

SPOROBOLUS. A genus of exotic grasses of the agrostis tribe. Three annual species, a biennial, and a perennial have been introduced to Britain from Australia and the two Indies; and they vary in height from 6 to 30 inches, and thrive in any common soil, and are all propagable from seeds; but they are more curious than useful.

SPRAIN. See STRAIN.

SPRAT. See FISH and RUSH.

SPRENGELIA. A small genus of ornamental exotic plants, of the epacris order. The flesh-coloured species, *S. incarnata*, is a small evergreen shrub of 2 or 2½ feet in height; and carries flesh-coloured flowers from April till June; and was introduced to the greenhouses of Britain about 55 years ago from Australia.

SPRING. The season which intervenes between winter and summer. It is the season of revival to dormant animals and sleeping plants, —of germination to seeds and arousal to roots and stems,—of upstarting to grasses and ex-foliation to trees,—of begun glee and singing to the songsters of the grove,—of transition from gloom and snow-storms to cheeriness and warmth and sunshine,—of the outburst of hope and activity from the outhouses of the farmery to the fields of the farm,—and of the commencement and large performance of the busiest and most significant processes of cultivation. But we have sufficiently indicated its phenomena and its peculiar occupations in the article CALENDAR; and we shall here do no more than quote from "Mudie's Spring" a description of the prognostics, characteristics, and sequences of a spring snow-storm, embodying the most intensely interesting group of meteorological events which can challenge the farmer's attention from beginning to end of the year:—

"On an evening, after a day of unwonted tranquillity, dense clouds appear like great snowy mountains in the western part of the horizon, while the few clouds which lie in streaks across the setting sun, are intensely deep in their shadows, and equally bright in their lights. As the evening closes in, the clouds disappear, the stars are unusually brilliant, and there is not a breath of air stirring. The old experienced farmer goes out to take his wonted nocturnal survey of the heavens, from which long observation on the same spot has enabled him to form a tolerably correct judgment of what will be the state of the weather in the morning. Two or three meteors,—brilliant, but of short duration,—shoot along a quadrant of the sky, as if they were so many bright lights of the firmament dropping from their orbits. He returns and directs his men to prepare for what may happen, as there will certainly be a change of the weather. The air is perfectly tranquil when the family retire to their early pillows, to find that repose which healthful labour sweetens and never misses,—

> 'Till rest, delicious, chase each transient pain,
> And new-born vigour swell in every vein.'

But just at the turn of the night, the south gives way, the north triumphs, and the whirlwind, herald of victory, lays hold of the four corners of the house, and shakes it with the shaking of an earthquake. But the house, like its inhabitants, is made for the storm, and to stand secure and harmless; while the wind thunders in the fields around, every gust roaring louder than another amongst the leafless branches of the stately trees. In a little its sound is muffled, without being lessened, and the snow is heard battering at the windows for an entrance,—but battering in vain. Morning dawns; but every lea and eddy is wreathed up; the snow still darkens the air, and reeks along the curling wreaths as if each were a furnace. For two days and two nights, the storm rages with unabated violence; but on the third day, the wind has veered more easterly, blows rather feebly, and though the snow falls as thickly, it falls uniformly over the whole surface. This continues for two or three days more; and on the coming of the last of these days, the sun, which has not been visible for nearly a week,

looks out just before setting, as if promising a morning visit. The night remains clear, with keen frost, and the wind steady at north, and blowing very gently. The sun rises bright in the morning,—the storm is over,—and the weather remains unbroken for four or five weeks. When the appointed days of the snow-storm are numbered, a disturbance again takes place in the atmosphere, but it is of a different kind from the former. There are little sheets of lightning playing momentarily in the lower atmosphere, and the lustre of the stars is diminished; but still there is no cloud. The wind, however, dies away to a dead calm towards evening, and all is ready for the breaking storm. That operation is the first performed by the spring, and we shall borrow the words of the 'British Naturalist' wherein to describe it:—'As the spring gets the mastery, which is aided by the condensation which takes place during the night, it rises to a wind, the sound of which cannot be mistaken. The rigidity of trees, window-frames, and other wooden fabrics through which it passes, is relaxed; the withered grass and reeds, when these are exposed, moisten; and the rattling and thumping are succeeded by murmuring harmony, in which, compared with the other, there is a good deal of music, and as the morning advances, and the animals come abroad, and man begins to be active, the hard metallic sounds are gone, and there is a softness about nature. There is always a delightful transparency about the atmosphere, because the little *spiculæ* of ice are gone, and the heat of the air is too much occupied in converting the snow and ice into water, for changing much of that into vapour. When the change is accompanied by rain, it is far more pleasant at the time, and there is a danger, almost a certain one, that the spring will be treacherous; and that, in consequence of the great heat required for melting the snow, and the evaporation of the rain together, frosts will return long before the process of thawing, so comparatively slow, is completed. The slow melting of snow by rain compared by that of a warm atmosphere, which is constantly shifting by the wind, can be easily understood when it is remembered that the water which falls, even if it had the temperature of the greatest summer-heat, would be cooled down to the freezing point in melting half its weight of snow. But as the temperature can only be a little above freezing, the water will have the temperature of 32° before it has cooled perhaps one-tenth of its weight; and as the water is a bad conductor of heat, and great part of the action of the oblique rays of the sun is reflected away from its surface, a rainy breaking of a storm is almost sure to be followed by frost, if it do not happen when the season is far advanced.' In such a situation, and under such circumstances, the storm not unfrequently passes away in what is emphatically termed a gentle thaw; and when this is the case, the spring comes under the most favourable circumstances. The snow is dissolved by atmospheric influence alone, without any rain from the clouds; although there are generally light clouds hovering about, ready to produce rain if a returning frost should render a contest of the elements necessary. Besides its rare pleasantness, the gentle thaw is attended with several beneficial consequences. In the first place, there is no flooding of the low grounds, and no washing of the soil from the more elevated ones; but the snow forms a trough for the discharge of the water into which it is melted, and thus the coldest of the snow-water does not reach the surface of the land. In the second place, the water produced by the melting of the snow sinks gradually into the earth, and the earth has been opened to receive a greater store than if it had been pelted by rain during winter. This is occasioned by the radiation of the heat from the lower strata of the earth, which is confined by the snow, and turned back again to act upon the earth. In the third place, this last circumstance produces a beginning of the spring under the shelter of the snow, which could not have taken place with free exposure to the atmosphere. The blade of the plant is protected, and the roots have heat and moisture, and the air is excluded from them. They are thus placed under the most favourable circumstances, and they are stimulated accordingly. The difference in this respect is very considerable; for if, owing to the action of the wind during the fall, or to any other cause, one portion of a field has been exposed to the air while the frost continued, and another covered by the snow, it will be found that vegetation upon the part which the snow covered will be fresh, green, and vigorous, long before that upon the exposed part shows any decided signs of action. This, by the way, is the real cause why spring is so much more rapid, and meets with so fewer reverses, where the winter is firm and decided, but of moderate length, than it does when the winter is variable."

SPRING. A natural fountain,—a stream of water issuing from the ground. It is fed by the percolation of surface water through porous strata in an elevation somewhere above it, and is caused by the obstruction or accumulation of the percolating water on a retentive stratum, forcing it along to find a vent in the crevice or porosity where the spring is situated. See the articles Artesian Well and Geology, and the section "Strata-Draining" of the article Draining. A spring may have any volume from a mere thread of water to an incipient river, according to the extent of percolating surface which it drains and to the moistness of the climate; and it may be either occasional, seasonal, or perennial, according to the circumstances of the percolation and the nature of the ground. Most springs, especially on hill sides and in upland districts, are cool and of comparatively uniform temperature, in consequence of the percolation which feeds them passing through great depths or wide expanses of strata, which are affected

little by solar heat, and not at all by subterranean heat; but some, especially in the vicinity of active volcanoes, or in districts subject to the action of earthquakes, where the percolation proceeds within the range of the subterranean fires, constantly possess a high temperature; and almost all springs, whether cold or hot, hold in solution, more or less abundantly, in more or less variety, and with more or less perceptibility in taste and colour, mineral substances derived from the strata through which the percolation occurs. See the articles WATER, MINERAL WATER, IRRIGATION, and FOUNTAIN.

SPRING. A mechanical contrivance for resisting percussion, regulating pressure, diminishing draught, or producing interior motion. It combines in a high degree strength and elasticity; and may consist of elastic steel or any similar substance. The spring of a watch is a familiar instance of a spring producing interior motion; and the springs of carriages, in all their numerous varieties, serve one or two or all of the three other purposes of springs. "Springs," says Mr. Giddy, "were in all likelihood first applied to carriages with no other view than for the accommodation of travellers; they have since been found to answer several important ends. They convert all percussions into mere increase of pressure; thus preserving both the carriage and the materials of the roads from the effect of blows; and small obstacles are surmounted when springs allow the frame and wheels freely to ascend, without sensibly moving the body of the carriage from its place. If the whole weight is supposed to be concentrated on springs very long, extremely flexible, and with the frame and wheels wholly devoid of inertia, this paradoxical conclusion will most certainly follow,—that such a carriage may be drawn over the roughest road without any agitation, and by the smallest increase of force. It seems probable that springs, under some modification of form and material, may be applicable with advantage to the heaviest waggon." "All stage coaches, and many travelling carriages," says Mr. Youatt, "hang upon grass-hopper springs, which allow of perpendicular without any longitudinal action. The more elasticity, or in other words, the more action there is in grass-hopper springs, the more effect it will produce in diminishing the draught; with a C spring a very contrary effect is produced. A carriage hung upon C springs may certainly be made the most comfortable to the rider; but all the ease that can be required, and much more than is found in the generality of post-chaises, may be obtained by well-constructed grass-hopper springs, and with considerable advantage to the horses. The practice of loading coaches as high as possible to make them run light, as the coachmen have found by experience, is only a mode of assisting the springs. The mass being placed at a greater height above the wheels, at the extremity of a long lever, is not so easily displaced laterally by any motion of the wheels, which, therefore, rise and fall on either side as they run over the stones, acting only on the springs, which restore the full pressure and velocity in descending, from the obstacle which was imparted to them in ascending, and without producing any sudden concussions upon the load, which swings to and fro with long easy movements. It is possible, also, that the weight, being thus swung from side to side, may, upon good roads, diminish the draught, as it is in fact generally running upon two of the wheels; while, in the other direction, it equally admits of the front and hind wheels successively passing over any impediment; and yet, by the manner in which it is fixed upon the springs, it does not admit of any longitudinal elasticity."

SPRING-FEED. Though the use of turnips in winter, and of artificial grasses on arable land in summer, has been carried to a high degree of perfection, yet a full, proper, systematic supply of succulent feed for young stock and for all non-fattening cattle, between the finishing of the turnips and the commencement of the grasses, is still, in a considerable degree, a desideratum; and this is what many farmers technically call spring-feed. Swedes have done much to afford the supply; but however palatable and nutritious for the main portion of stock, they entirely fail for the young, and do not always last long enough for the old. Every judicious breeder is desirous of training the young stock to keep themselves as soon as there is food of a proper quality available for them; and if the young lambs in particular are kept from green food until they are turned into the grass clover leys with their dams, there is great danger that a portion of them will be lost. It is generally desirable to keep the clover leys free at least until May, and long before that time the young stock should be trained to eat a considerable portion of green food. With the view of supplying this want, several plants have been cultivated for early feed in the spring, with greater or less success, or under greater or less disadvantage. The farmer who occupies a poor soil encounters peculiar difficulties; for lateness of vegetation and certain destruction of his crops of grass are sure to be the consequence if he break into them before they attain a proper degree of maturation, and yet he has also the greatest obstacles to surmount in cultivating any spring crop. The farmer, on the other hand, who cultivates rich fertile land where he has a deep alluvial soil, growing every crop luxuriantly, can easily free a pasture early in the autumn, and have it full of young grass as early as he may require it, and knows nothing of the difficulties which attend his less favoured neighbour. The avidity with which any new kind of forage plant promising early growth is tried, indicates how desirable a point it is to secure an early supply of succulent food. The crimson trefoil was tried;

but has generally been found a failure. Young furze is suitable enough on some store farms, for sheep of very hardy constitution; but is of very limited value in other circumstances. The winter tare is eminently useful, and affords a very great bulk of nourishment; but is rather a summer than a spring crop. A series of forage crops suitable alike for green food and for hay is of the highest consequence; but belongs rather to the system of soiling than to the simple provision of spring-feed. Some forage plants, as white mustard, make excellent feed for sheep, but are not equally suitable, or even not suitable at all, for cattle. Altogether, the best plants as yet tried for spring-feed are the luxuriant varieties of rye. See the articles Rye, Soiling, and Feeding of Animals.

SPRING GRASS. See Anthoxanthum.

SPRING WHEAT. See Wheat.

SPRIT. See Rush.

SPROUT-HILL. See Ant.

SPRUCE. See Fir.

SPUR. See Ergot.

SPURGE. See Euphorbia.

SPURGE LAUREL. See Laurel (Spurge).

SPURGE OLIVE. See Mezereon.

SPURLESS VIOLET. See Violet (Spurless.)

SPURREY,—botanically *Spergula*. A genus of herbaceous plants, of the carnation family. The calyx is five-segmented; the petals are entire and amount to five; and the seed-vessel is ovate, five-valved, one-celled, and many-seeded. Five species grow wild in Britain; several have been introduced from other countries; and a number more are known.

The common spurrey, or yarr, or pickpurse, *Spergula arvensis*, is an annual weed of the sandy corn-fields of Britain. Its stems are lax, spreading, jointed, angular, leafy, moderately branched, hairy and viscid in the upper part, and from 6 to 15 inches high; its leaves are whorled, subulate, narrow, obtuse, fleshy, and downy, and have short stipules; its floral footstalks are slender and downy, and become reflexed toward the period of the seed ripening; its flowers are white, and bloom from June till August; and its seeds are somewhat kidney-shaped, angular, rough, and of a black colour. This plant abounds on inferior light soils, which have been too finely tilled; and it is greedily eaten by all sheep and cattle, and appears to be very nutritious and wholesome, and is said to improve the mutton of sheep and the milk and butter of cows. Two very distinct varieties of it are much cultivated in Germany and Flanders as late pasture for sheep and cattle,—the one with large smooth seeds, called *S. a. sativa*,—and the other with a somewhat freely branching habit, called *S. a. ramosa*. The herbage continues green till a late period in autumn, and often throughout the winter; and it can either be used as pasture or cut for soiling or made into hay. The seeds also afford by expression a good lamp oil, and may be ground into flour which, when mixed with the flour of wheat or rye, is suitable for bread, and is often employed for that purpose in Gothland and Norway. Poultry eat spurrey in any form, and are thought to become very prolific of eggs when fed upon it. Von Thaer speaks of it as an eminently nutritious herbage; and not a few Continental agriculturists seem to think it an excellent crop. Notwithstanding all its recommendations, however, it does not appear to merit cultivation in Britain. We possess much more profitable plants for all the soils and situations which it would suit; and we have sometimes a great deal more than enough of itself in the unwelcome form of a weed.

The pentandrous spurrey, *Spergula pentandra*, is an annual weed of the sandy fields of some parts of England; and it has a height of 6 or 8 inches, and carries white flowers in June and July.—The knotty spurrey, and the awl-shaped spurrey, *Spergula nodosa* and *Spergula subulata*, are perennial weeds of the sandy heaths of Britain; they have a height of 6 or 8 inches, and carry white flowers in the latter part of summer.—The sagina-like spurrey, *Spergula saginoides*, is a perennial-rooted, creeping indigen of some of the lofty mountains of Scotland; and it carries white flowers from June till August.—Two of the introduced species,—the pale, *Spergula pallida*, a reddish flowered evergreen herb, from the Cape of Good Hope, and the larix-like, *Spergula laricina*, a white-flowered, tiny trailer, from Siberia—have an ornamental character, and deserve a place in the flower-border.

SQUASH. The melon-pumpkin,—*Cucurbita melopepo*. See the article Gourd.

SQUEAKER. A pigeon under six months of age.

SQUILL,—botanically *Scilla*. A genus of ornamental, bulbous-rooted plants, of the asphodel family. Four species grow wild in Britain; upwards of twenty have been introduced from other countries; and some more are known. They have radical and somewhat linear leaves; and carry their flowers in clusters, on the top of solitary naked flower-stalks; and look, in many instances, like miniature hyacinths; and have, in general, a very pretty appearance. Most have either blue or red or pink or white flowers; the great majority love a light soil, either of peaty loam or of sandy loam; and all are readily propagated from offsets.

The undescribed squill, or wild hyacinth, or harebell, *Scilla non-scripta*, abounds in the woods and groves and streamlet banks of many parts of Britain; and is one of the most beautiful of our wild flowers; and also holds a conspicuous place in many a flower border. Its flower-stem has commonly a height of about 8 or 9 inches; and its flowers are blue, and bloom from March till June. One variety of it, *S. n. alba*, has white flowers; and another, *S. n. carnea*, has flesh-coloured flowers. Its bulb, in common with that

of most or all of the other species, contains some acrid or poisonous matter,—whence is derived the names squill and scilla, from a word signifying to injure; but it also contains much useful mucilage, which can easily be separated from the acrid matter, and is extensively employed by calico-printers.—The spring squill, *Scilla verna*, grows wild in rocky situations in Britain; and has a height of 3 or 4 inches; and carries blue flowers in April and May. Two pretty varieties of it—the one with white flowers, *S. v. alba*, and the other with rose-coloured flowers, *S. v. rosea*—occur in gardens. — The two-leaved squill, *Scilla bifolia*, grows wild in the woods of some parts of England; and has a height of 3 or 4 inches; and carries blue flowers from February till April. Two varieties of it—the one with white flowers, *S. b. alba*, and the other with red flowers, *S. b. rubra*—have been introduced from the south of Europe.—The autumnal squill, *Scilla autumnalis*, grows wild in the dry pastures of some parts of England; and has a height of 3 or 4 inches; and carries pink flowers in August and September. Two varieties of it—the one much taller than the normal plant, *S. a. major*, and the other with white flowers, *S. a. alba*—occur in gardens.

Some of the most beautiful, or otherwise interesting, of the introduced species, are the campanulate, *S. campanulata*, a native of Spain, a foot high, carrying dark purple flowers in May and June, and comprising two varieties with respectively white and pink flowers; the Italian, *S. italica*, a native of Switzerland, 9 or 10 inches high, carrying blue flowers from April till July; the Peruvian, *S. peruviana*, a native of Southern Europe, a foot high, carrying dark blue flowers in May, and comprising a variety with white flowers; the Siberian, *S. sibirica*, a native of Siberia, 3 or 4 inches high, carrying blue flowers in February and March; the pleasing, *S. amœna*, a native of the Levant, 3 or 4 inches high, carrying light blue flowers in March and April; the hyacinth-like, *S. hyacinthoides*, a native of Madeira, rather tender, 6 or 7 inches high, carrying blue flowers in August; and the esculent, or quamash, *S. esculenta*, a native of North America, a foot high, carrying white flowers from May till July.

SQUILL ROOT. The bulb of *Ornithogalum squilla*. See the article ORNITHOGALUM. This bulb is medicinal, and has a place in the pharmacopœias. It is inodorous, bitter, and nauseous; and possesses so much acridity that, when much handled, it inflames and ulcerates the skin; but loses a considerable portion of both its acridity and its medicinal virtues by drying and long keeping. It consists, according to Vogel, of 30 per cent. of woody fibre, 24 of tannin, 6 of gum, 6 of saccharine matter, and 35 of a peculiar bitter principle called scillitina; and this principle, when separated, is white, transparent, and pulverulent, breaks with a resinous fracture, is very soluble in water and in alcohol, rapidly absorbs moisture from the atmosphere till it liquefies, and has an intensely bitter taste with a perceptible degree of sweetness. Squill root, in small dozes, is expectorant and diuretic,—in large doses, emetic and purgative,—and in over-doses, productive of strangury, bloody urine, cold sweating, and convulsion; and it is administered, in combination with other medicines, in asthma, dyspnœa, and dropsy, — and is also a principal ingredient in a number of expectorant pharmaceutical preparations, ordered in the pharmacopœias and kept in the drug shops.

SQUIRREL. A genus of mammals, of the order rodentia. They have four grinders, variously tuberculated, and a very small additional one above in front,—strongly compressed inferior incisors,—large head, with lively projecting eyes, —four toes before, and five behind, the thumb of the fore-feet sometimes marked by a tubercle,—and a long tail, furnished with hairs, and, in the case of the most characteristic, so spread out on the sides as to resemble a large feather. They are light and active animals, living on trees, and feeding on fruits.—The common squirrel, *Sciurus vulgaris*, is a well-known, lively, little inhabitant of the woods of Britain. Its back has a bright red colour; its belly is white; and its ears are terminated by a tuft of hair. It feeds on nuts, acorns, cones, buds, and young shoots of trees. The female constructs among the branches of trees a nest of moss and dried leaves, and brings forth from three to seven young in April or May.

SQUITCH-GRASS. See COUCH-GRASS.

STAAVIA. A genus of ornamental, calyciflorous, white-flowered, Cape-of-Good-Hope, evergreen undershrubs, of the brunia family. Three species, varying in height from 12 to 24 inches, and blooming in the early part of summer, have been introduced to the greenhouses of Britain; and they are heath-like and beautiful, and love a soil of peaty loam, and are propagated from cuttings.

STABLE. The size, arrangement, and furnishing of stables must considerably vary according to the circumstances of their owners, and to the number and quality of their inmates; and yet ought, in every instance, to be determined by certain great general rules for the promotion of convenience, cleanliness, ventilation, comfort, and health. Some hints for wisely constructing them on farm-steads are given in the article FARM-BUILDINGS; and instructions respecting their efficient management are contained in the articles HORSE, GROOMING, LIQUID MANURE, and FARM-YARD MANURE; so that, in this place, we have to concern ourselves principally with the statement and illustration of the most important of the general rules.

The site of every stable ought to be such as to ensure complete drainage, not only of all rain and snow water, but also and stringently of all

liquid affusion within, and especially of all urine. A perfectly and constantly dry stable is quite essential to the health and vigour of horses. "But," to adopt the words of Mr. Winter, "this is not the sole reason why the urine should be speedily conveyed away, for it not only keeps the flooring in a damp state, but fills the stable with gases highly deleterious to the health of the inmates, frequently acting as the predisposing or exciting cause of dangerous and contagious diseases, as acute and chronic cough, pneumonia, farcy, glanders, and inflammation of the conjunctival membrane of the eyes. It usually happens that the fluids of the stable are allowed to find their exit by an open paved gutter at the foot of the stall, or are suffered to be entirely absorbed by the litter, and removed with the dung when the stable is cleansed out. An under-ground drain, originating in a small grating fixed in the centre of each stall, and communicating with an external reservoir or cistern, is found the most ready and beneficial method of insuring the removal of the urine from the stable. This method saves the litter by keeping the floor of the bed constantly drained, it decreases the general dampness of the stable, and adds to the health and comfort of the inmates. In many of the cart-horse stables in London, a central iron grating is placed over a small cesspool, but no longitudinal subterranean conduit is constructed to convey the fluid away; consequently, when it is full, the grating has to be removed and the contents baled out. This is a very objectionable practice; for though the stalls and litter may be kept dry, yet these collecting cesspools are so many reservoirs of fermenting fluids, increasing the chemical decomposition, and poisoning the atmosphere of the stable with ammoniacal vapour. It is far preferable to have a continuous underground drain, from stall to stall, throughout the stable, terminating in a sunken external reservoir, so constructed as to preclude the indraught of air up through the drains. Another advantage is attached to this manner of drainage; for as the fluid drains from the centre, there is no longer any necessity for that declivity of the flooring, which was requisite when the liquid passed away by the foot of the stall, for the ends and sides of the pavement of the stall may be of the same level, gradually bevelling towards the centre point where the grating is fixed."

The size of stables must be proportioned to the number of horses to be accommodated; but that of each, even when the number of horses is great, ought not to contain accommodation for more than five or six. Some horses will not sleep or even lie down unless perfectly at their ease; and when too many are in one stable, they are liable to disturb one another, and to be annoyed by the frequent entrance of persons in charge of them, and to suffer excessive contamination and heating of the air, so that they may have difficulty in going to rest, and cannot enjoy the most refreshing repose. The livery stables attached to many large inns in towns often exemplify the evils of disturbance consequent on too large capacity. The ceiling or roof ought, in every case, to be high, so as to allow a free ascent of the heated and contaminated air; and, in general, walls eight feet high, with the space above open to the roof, are preferable to even higher walls with a close ceiling. Double-headed stalls are objectionable, both on account of their allowing the stables to be crowded, and because the horses in them may hurt each other by kicking and collision. The size of stalls must correspond in some measure to the description of the horses kept in them; but, in every instance, ought to be wide enough to allow them to turn round without injuring themselves, and yet not so wide as to allow them to stand across; and, for each working farm horse, may be 6 feet or at the least 5½. The width of the stable from wall to wall ought to be such as to afford not only quite clear space for all the proper accommodations, but also a space of several feet behind the horses for the passing and working of the grooms. The floor should consist of granite causeway, hard brick, Dutch clinker, wooden blocks, patent elastic caoutchouc pavement, or of some other material which will firmly maintain a general level, and resist abrasion from pawing, and not subside into chinks or depressions.

When a hay-loft exists over a stable, it ought to be high and separated by so impermeable a flooring or ceiling as will completely prevent the escape into it of effluvia from below; but a hay-loft over a stable, no matter how well constructed, is, in all circumstances, exceedingly undesirable, both for sake of the sweetness of the hay and of the ventilation of the stable. "The rack and manger have long been regarded as essential structures in the fitting up of stables, and are still very generally employed; but when the better and more economical plan of cutting the fodder is adopted, the rack will become unnecessary. Upright racks are to be preferred to those inclining forwards, as, in the latter case, the horses are often much annoyed by the small seeds falling into their eyes and ears in drawing out the hay. Racks and mangers are very frequently constructed of cast-iron, and these are found much more durable and economical than those formed of wood. Under each window may be a recess for holding an oil-can, or vessel with tar; and, if provided with a door, it may be used for holding the combs and brushes which are employed in cleaning the horses. Every part of the harness in daily use should be placed behind the horse to whom it belongs, in order that no time may be lost in taking it off and putting it on; and that which is used only occasionally is to be kept in a separate lock-up apartment. There should be one or more lanterns suspended by cords and pulleys over the passage, for putting lighted candles in while feeding and cleaning

the horses during the winter. The loft being condemned in farm stables, a place must be provided for holding the food and litter; the most convenient will be one or two divisions opposite the door, into which the food, whether green clover or tares in summer or hay or roots in winter, can be readily carried from without, and easily distributed within. Being near the door, the food will be better ventilated than it could be in any other part of the stable, and it will occupy the least valuable part with reference to the horses; it being well known that the horse that stands opposite to the door is more liable to take cold than any other. The corn-bin or chest may also be kept in one of these divisions, and it ought to be large enough to have separate apartments for corn and beans, and for cut straw or hay, or bruised furze, to mix with the corn or pulse. The door-ways should be 4 feet wide and 7 feet high; and the door must not have any projecting latches or handles, because they are apt to hurt the horses, or become entangled with the harness in passing out and in." [Sproule's Treatise on Agriculture.]

A good degree of light in a stable, though not so much as to be glaring, promotes the comfort of horses, acts as a preservative of their sight, and prompts their keepers to maintain cleanliness and ventilation. Where little light is admitted, the walls should be frequently whitewashed; and where too much or even a moderate degree is admitted, they should be painted grey. One or more windows should exist in every farm-stable, according to the size; and each should consist of two sashes, moving up and down by pulleys, or sliding past each other in grooves, and should be glazed with small panes in leaden divisions, and protected by a luffer-boarding, with the laths placed in a horizontal position.

The maintaining of purity of air in a stable, by means of cleanliness and ventilation, is essential to the health and vigour of horses. Scarcely one farm-stable in fifty is thoroughly cleaned out even once a-week; and the noxious effluvia from the accumulation of excrements, litter, and frequently green food of various kinds, in different stages of decomposition, constantly exercise a baneful influence on the blood of both the horses and their keepers. The purer the atmosphere in which any animal is kept, the more vigorously and the more healthily will every function of the different organs of the body be performed, and consequently the inhalation of air impregnated with the stench of vegetable matter in a state of putrefaction, by corrupting the blood with which it comes in contact, vitiates every secretion of the body, and in time, if it cause not actual disease, which is most probable, never fails, at all events, to produce languor and debility. The gases arising from the excrements of horses, too, act prejudicially upon the eyes,—a fact of which any person who will remain in a foul stable while it is being cleaned may practically assure himself. Every farmer ought personally to superintend the care of his horses, and to insist upon his stable being daily cleaned out; and this operation, if regularly performed, will in the end occasion far less trouble than when filth of every kind is allowed to accumulate for days. The breeder of valuable horses in general is considerably alive to the necessity of attention to his young stock, while the man who has only an occasional colt or filly leaves the goodness of it pretty much to chance; yet the principle of obtaining for every horse a due supply of fresh air, and of keeping him in an atmosphere unimpregnated with noxious vapours of any kind, is the same as far as regards the purposes of health, whether a horse be worth ten pounds or a hundred. During the act of respiration one of the component parts of atmospheric air becomes destroyed by coming in contact with the carbon of the blood; and hence the air that is expired from the lungs, if inhaled again without admixture with fresh air, is deficient in those particles which should effect the chemical change in the blood, so necessary to life. For this reason, as well as on account of not allowing the noxious gases to escape, air-tight or closely shut stables are highly injurious to horses; and yet the practice of stopping up every aperture at night and excluding the air is very generally adopted by great numbers of people, alike ignorant of the injury they thus inflict upon their horses, and of the mode in which their superabundant and ill-directed care operates prejudicially upon animal life. Many men, too, while endeavouring to put valuable horses in condition prior to offering them for sale, are in the habit of thus coddling them up, with a view to improve the appearance of the coat,—an advantage which is frequently gained only at the risk of exciting inflammatory disease, and always with the loss of some portion of that sprightliness of movement and general vivacity so indicative of health and vigour. Yet mere perviousness to the air from the looseness of the doors or the craziness of the walls is very far from affording sufficient ventilation; and occasional free admission of the air by leaving the doors or the windows some time open may make such sudden changes of temperature or establish such strong cold currents as will seriously expose the horses to colds and inflammations. Apertures for the egress of the foul gases should exist in the roof or on the top of the walls; and apertures for the ingress of fresh air should exist near the floor;—and both should be covered externally by a grating, and so contrived as to be capable of graduation.

The littering of stables ought to have reference to the repose of the horses' bodies during the night and to the protection of their feet from unequal pressure on the floor during the day; and therefore it ought in all stables to be more or less removed every morning,—in stables with

perfectly sound and even floors, wholly removed, —and in stables with cobble-paved floors, allowed to remain just in sufficient quantity to protect the feet. "If retained," remarks Mr. Winter, "it prevents the quick and perfect drainage of the stall; it heats the feet and legs, causing a rapid wiring-in of the heels, contraction, thrushes, cracked heels, and swelled legs. A bed in the daytime entices the animal to lie down too much, and often provokes foul feeding. Some of our cavalry stables are a disgrace as well as a loss to the country. At the dictate of the commanding officer, who possibly likes to see the horses 'comfortable,' they are kept constantly bedded up to their knees: the result is, that there is scarcely a horse fit for actual service in the regiment. If attempts were made purposely to produce disease of the extremities, none could be found more destructively efficient than this baneful practice. Many of the evils which are falsely attributed to concussion, hard roads, bad shoeing, &c., are the evident results of this unnatural manner of keeping the feet. Veterinarians who wish to act honourably by their employers, should be loud in their remonstrances against the continuation of this destructive stable custom. It is their duty to point out its injurious tendency. The most ancient writer on cavalry affairs extant, Xenophon, is specific on this point. He says, 'It is good to enjoin the groom to carry out to one place, every day, the dung and straw from under the horse. When he does this, he will remove it with the greatest ease, and, at the same time, do a benefit to the horse.' The Arab litters his khayle with a shallow bed of dry horse-dung, which is daily removed and exposed to the sun: a similar practice obtains throughout Persia. In Egypt the floor of the stable is covered with fine desert sand, which is repeatedly changed, and never allowed to be saturated with moisture; and in no country in the world are the feet and legs of horses more free from disease." The rapid removal of ammoniacal vapours may be greatly aided by strewing gypsum on the floor, or by placing a thin layer of charcoal slightly moistened with sulphuric acid on a board or slab in some part inaccessible to the horses; and when the substance thus used becomes saturated with ammonia, it is a rich manure, and may either be employed alone as a dressing for almost any crop, or mixed with guano. The temperature of every stable should be regulated by means of the ventilators, and ascertained by means of a thermometer, and kept at about 55° in winter and between 60° and 65° in summer.

Every stable ought to be so framed, as to be convertible in a few minutes into loose boxes, and as easily reconvertible into its proper character; and this may be effected principally by the simple contrivance of having every alternate partition moveable. Or, at all events, two stalls in every stable ought to be convertible into a loose box by the removal of the intermediate partition. The occasional placing of horses in loose boxes instead of stalls serves some eminently useful purposes in ordinary stable management, and is a powerful therapeutic measure in all cases of injury from over-exertion, and in many kinds of the most ordinary diseases; and it is not only becoming more general than formerly in all sorts of well-managed establishments, but is even regarded as essential to the economy and the good conduct of every stable of proper character. "It would be well," remarks Delabere Blaine, "were in-door horses more generally accustomed to spend their leisure time in boxes than stalls. Boxes are advantageous to the jaded horse, by encouraging him to lie down during the day; they are advantageous to the idle horse, by encouraging him to exercise himself. By means of boxes, the evils of long frosts to the hunter are avoided, and the unrestrained enjoyment of freedom is relished by all. A loose box wholly unconnected with the stable is also a valuable appendage to a gentleman's establishment,—it may thus with impunity be the receptacle of a contagious case. The detached box should be so constructed as to be capable of being cooled to nearly the temperature of the external air, or, when necessary, to be made as warm as requisite for some cases of sickness. No projections should be allowed in its walls to hurt the hips in cases of falling from weakness, staggers, &c. It should, also, have a grate in the centre communicating with an outer cesspool, with a general slight leaning of the flooring to the grating. Into a large box of this description every horse taken up from grass should be first put, to prevent the access of the worst colds to which horses are liable, which are those caught on the sudden removal from a cool into a heated temperature."

STACHYS. See HEDGE-NETTLE.

STACHYTARPHETA. A genus of ornamental, exotic plants, of the verbena family. Nearly a dozen species have been introduced to British gardens from Ceylon, Cayenne, the West Indies, and South America; and several more are known. The introduced species comprise annuals, biennials, herbaceous perennials, and evergreen shrubs; they vary in height from 12 to 40 inches; three carry respectively white, orange, and violet flowers, and all the rest carry blue flowers; and most bloom in summer, and love a soil of peaty loam. The popular name of some of the earliest known kinds is bastard vervain.

STACK. A large pile of sheaf-corn, hay, turf, or other matter built and thatched for protection from the weather. But piles of hay are more properly called ricks, and piles of turf more properly turf-stacks; and piles of sheaf-corn formed at the time of harvesting, and generally situated in the yard immediately adjacent to the barn, are the chief and truest stacks. These vary in form and size according to the usages of dis-

tricts, the taste of farmers, the extent of crops, and the circumstances of farms. Long, narrow, quadrangular stacks are preferred, in some instances, for convenience of erection, firmness of structure, pleasantness of appearance, and economy of thatching; but circular stacks, of 12 feet or upwards in diameter, with either a cylindrical or a gradually widening body, and with a roof or head in the form of a cone, are found, in the aggregate of enlightened experience, to comprise the greatest amount of advantages.

The old stool or foundation used for a stack was either a quantity of loose dry straw, laid on dry ground or bedded on brushwood, or a compact layer of dry boulders or other large stones; but that now in use, in all well-managed farms, is a stand, staddle, frame, or platform, of the same diameter and periphery as the stack, supported on feet or short pillars of either wood, stone, or iron; and this serves the three-fold purpose of preserving the stack from the depredations of rats and mice, of protecting it from the moisture of the ground, and of admitting the air from below to circulate through its body and to maintain it in sweet and sound condition. In beginning to form a circular stack, a sheaf is placed upright on its butt end, as nearly as possible in the centre of the stool; and around this other sheaves are placed in circles, likewise upright, but with a small inclination of their tops inwards. Circular ranges of these upright sheaves are continued till nearly the whole stool is occupied. The stacker then begins to place his outside row of sheaves, bending them by means of his knees, so that their butts become somewhat horizontal from the band downwards, while their heads lean obliquely upwards and inwards against the outer range of the upright sheaves. He continues to lay on circular layers of sheaves, their butts all outwards, till he has raised the outside of the stack nearly to a level with the tops of the original upright sheaves, which are now all forced into great obliquity inwards, and into considerable consolidation. He then fills up the heart of the stack; in doing which, he does not place the sheaves in any very exact order, yet so arranges all as to fill up the space equably, the centre or heart being always highest, and the corn ends of the sheaves inwards, every sheaf or row of sheaves having a regular and obvious slope downwards and outwards towards their butts. The stacker never steps upon the central part of the stack; and, in consequence, that part is always left comparatively open, or less compressed than the exterior of the stack,—all the sheaves of which are pressed down by his weight. He now forms a circular row of sheaves about 15 or 18 inches within the outside circle; and this is very carefully laid sloping outwards and downwards at its butts, and upwards at the ear-ends, which rest or ride upon the heart of the stack. After this he again fills up the heart. He next lays a new outside circular row, the ear-ends of which are obliquely elevated by the butts of the former inner row; and he continues to lay alternately outside rows, heart rows, and heartings, always carefully preserving a considerable central elevation, by which all the butts in the whole composition of the stack have an obliquity outwards and downwards. In forming very large stacks, or when the straw is very short, there may be two or even three or more series of heart-rows, overlapping each other as already described, and all carefully constructed under the proper precautions, by which the penetration of rain into the stacks is effectually prevented. In the formation of all the circular rows, the stacker works upon his knees, pressing down every successive sheaf into its place by the application of his weight; and to ensure regular equality in building, he always begins a new circular row at a different place from where the former terminated. When he has carried up his stack to the intended height, perhaps 10, 12, or 15 feet, he sets what in Scotland is called 'the easing gang,' or an outside circular row of sheaves, having the butts projecting a few inches beyond the body of the stack, and forming the eaves. After this, every successive row of outside sheaves is placed gradually more inwards, and the heart of the stack is always most carefully preserved higher than the outside row, and even a good deal more so in the head of the stack than while building the body, continuing or rather increasing the obliquity of the sheaves. When he has drawn the roof of the stack to a narrow circle or platform of 3 or 4 feet in diameter, he quits the kneeling posture in which he had hitherto worked, and places one sheaf upright in the centre of the small platform, filling the whole of that space with upright sheaves set around the centre one, and leaning a little towards it. He then gets a straw-rope, with the middle of which he firmly embraces these upright sheaves, by two or three turns of the rope, and the assistants fasten the two ends of that rope on opposite sides of the stack, so as to secure this conical crown of sheaves from being thrown over by the wind. A stack carefully built in this manner, and afterwards properly thatched, will bid defiance to any kind of weather, except a hurricane; and can even be very little injured by rain coming on before it is thatched; and no good farmer, unless from necessity, trusts his stack even for a day or two without thatching.

The best straw for thatching is that of rye, and the next best is wheat-straw; but, in defect of both, the straw of barley or oats must be employed. The straw must all be previously drawn, the short straws shaken out, the long straw laid parallel and bound up into sheaves, and the short straw made into bunches. In laying on the thatch, the thatcher stands upon the sloping conical roof of the rick, as near as he can to the eaves, and lays on the straw in handfuls, from sheaves placed within his reach. He thrusts the

inner end of his handful of thatch, gathered into a neck or wisp, into the butts of the sheaves, and spreads out the lower end like a fan, overhanging the eaves. Beginning at the eaves, and covering as much of these as he can reach at arm's length, he works upwards, causing each successive handful to overlap that immediately below; and he thus covers the roof in triangular portions, till he has gone round the whole backwards, that he may avoid treading on his work. When he has reached the top of all, he lays a considerable thickness of short straw upon the crown, over which a straw-rope is carried perpendicularly, dividing the roof into two equal sections. He then covers this topping of short straw with long thatch, drawn to a point at the summit, and ties the upper ends of this with a small straw-rope into a peak, giving this last part the resemblance of an umbrella. With the aid of two assistants on the ground, while he remains aloft on a ladder, so as to be able nearly to reach the top of all with his hands, the thatcher now places a number of straw-ropes, which obliquely embrace the conical roof, to secure the thatch. The middle of each rope is fixed, by means of a small wisp of straw, to the perpendicularly transverse rope already mentioned, and the ends of all the oblique ropes are fixed below by the assistants, either to the butts of the sheaves in the cylindrical body of the stack, or to a circular belt rope which firmly embraces the body below the eaves. If this is too high for the assistants, each has a short ladder to enable him to reach up. This series of ropes has a considerable obliquity from above downwards, and they are placed at about a foot or 15 inches distant from each other. In case of hurry from the prospect of bad weather, this first series of oblique ropes may secure the thatch from being blown off for some time; and in such emergencies, all the stacks belonging to a farm may be left for a time in this state. The whole fabric is effectually secured by a similar and opposite series of straw-ropes, put in the same manner on the other side of the roof, and obliquely crossing the first series of ropes. When thus finished, the entire roof is covered by a network of lozenge-shaped meshes, all the sides of every one of which are in a direction obliquely downwards, to facilitate the descent of moisture, either from rain or melting snow. A contrivance for promoting ventilation through the centre of a stack is noticed in the article Boss.

An oblong stack may be built with interruptions at regular intervals, for the convenience of taking it down in parts without disturbance to the remainder; and it is roofed in a ridge-form like a house, and is thatched similarly to a circular stack, but with the straw ropes stretched directly across. A main and very important objection to it, showing its vast inferiority to a circular stack, is its obstruction of the free circulation of the air, and its special liability to injury from the moisture of wet weather. The practice which prevails in some English districts of storing sheaf-corn wholly or principally in barns, is both inconvenient and very expensive. See the article Barn.

STACKHOUSIA. A small genus of exotic, monochlamydeous plants, constituting the type of the small natural order Stackhouseæ. Only two or three species have as yet been introduced to Britain; and all are from Australia, and but slightly ornamental. The flax-leaved stackhousia is an evergreen shrub of about two feet in height; and the one-styled is an evergreen shrub, of about one foot in height, carrying light pinkish flowers in April.

STACKYARD. See Farm-Buildings and Barn.

STADDLE. See Stack and Haymaking.

STÆHELINA. A genus of ornamental exotic plants, of the thistle division of the composite order. Its plants possess considerable affinity to the helichrysums and the finer kinds of gnaphaliums, and used formerly to be called wild immortal flowers. The doubtful species, *S. dubia*, is a hardy, deciduous, fragrant, purple-flowered shrub, about 3 feet high, blooming in June and July, loving a soil of peaty loam, and propagable from cuttings; and was introduced about two centuries ago from the south of Europe. Two frame, purple-flowered, evergreen shrubs have been introduced from Crete; and nearly a dozen other species are known.

STAFF-TREE. See Celastrus.

STAG. See Deer.

STAG-EVIL. See Tetanus.

STAGGERS. Several analogous yet widely different diseases of the chief domesticated animals. All are violent, and take their name from a staggering gait in their subjects, and require great promptitude and skill of treatment. The mad staggers of horses is phrenitis, and has been noticed in the article Inflammation. A similar staggers to this sometimes occurs in sheep and hogs, and ought to be similarly treated. The common staggers of sheep and oxen arises from the presence of a peculiar entozoon in the head, and has been noticed in the article Hydatid.

The stomach staggers or symptomatic staggers of horses arises from distention of the stomach with dry undigested food, producing pressure on the brain, and sometimes exciting inflammation in the intestines and the lungs. A horse affected with it hangs down his head, or rests it in the manger, appears drowsy, and refuses his food. His tongue and mouth are tinged of a yellowish colour; and commonly the membrane under his eyelid is more deeply tinged, and approaches in general to a dusky orange colour. A slight convulsive or twitching motion occurs in the muscles of the chest; the forelegs appear suddenly to give way at times, as if the horse would fall; and he rarely lies down, unless the disease is going off or death is approaching. The pulse is never affected in the early stage of this complaint, but sometimes begins to indicate by and

bye the commencement of inflammation. The disease is always attended with costiveness; and the dung that is drawn off by raking is generally hard and slimy. The urine is generally in small quantity; and in the latter stage of the disease, the jaw sometimes becomes locked. Stomach staggers never appears to originate in contagion or infection. When it occurs at grass it is generally about autumn, and frequently in meadows adjoining rivers, and other situations where the herbage is rank and innutritious; and when it occurs in stables, its seems to arise from the horse's eating too greedily, swallowing his food when imperfectly chewed, or eating freely of food that is difficult of digestion. Young vigorous horses may digest the most unwholesome food; but such as have been debilitated by hard usage, and are rather advanced in age, become very weak in their digestive organs, and when improperly fed are liable to stomach staggers. One of the best remedies is a mixture of a powerful stimulant with a purgative, such as a ball consisting of three drachms of calomel, two drachms of carbonate of ammonia, three drachms of ginger, six drachms of aloes, and a sufficient quantity of syrup. The hard fæces should be drawn from the rectum, and opening glysters injected. Some stimulating fluid, such as warm salt water with a little mustard or compound spirit of ammonia, should be given after the ball, and frequently repeated. When the fæces become soft, and the horse appears to be getting better, a drink of oatmeal gruel or of wheat-flour gruel may frequently be given to him, and a little cordial medicine may also be allowed; but, for a few days after his recovery, he must be fed with care, and not allowed any hay. One of the most effectual preventives of stomach staggers, is the plan now commonly adopted by brewers' servants, stage-waggoners, and all ordinary carters, of feeding with hay on the road, or carrying with them nose-bags.

Common or proper or idiopathic staggers in the horse is apoplexy, but is confounded sometimes with stomach staggers, and very generally with phrenitis; and it considerably resembles the latter disease in at once causes, symptoms, and cure. It commonly begins with an appearance of drowsiness, the eyes being inflamed and full of tears, and the appetite diminished. The disposition to sleep gradually increases; and in a short time the horse is constantly resting his head in the manger and sleeping. The pulse is seldom much altered; but, as in stomach staggers, costiveness and a defective secretion of urine are commonly present. Sometimes the disease will continue in this state for several days; at others, it assumes a formidable appearance very early, or even at its commencement, the horse falling down, and lying in a state of insensibility, or becoming violently convulsed. Sometimes a furious delirium takes place, the horse plunging or throwing himself about the stable, so as to render it dangerous for any one to come near him. The first stage of the complaint arises from an accumulation of blood in the vessels of the brain, which impedes in some degree the functions of that important organ; and if these vessels are not relieved by copious bleeding, there will be either an effusion of water in its ventricles, an inflammation of the membranes, or a rupture of some blood-vessel, and consequently an extravasation of blood. But sometimes there is so sudden a determination of blood to the brain, that these dangerous symptoms make their appearance before an effectual remedy can be applied. Bleeding is the grand remedy, and seldom fails of affording relief if employed with freedom at the commencement of the disease. It will be advisable also to give a purgative draft, and inject a stimulating glyster. If the symptoms do not abate in 8 or 10 hours after the bleeding, there will be great probability of obtaining relief by opening the temporal arteries, and suffering them to bleed freely; and if the disposition to sleep is not removed by the first bleeding, the head should be blistered, and a rowel inserted under the jaw.

Apoplectic staggers of cattle, sheep, and hogs, is closely similar to apoplexy of horses; but usually occurs when the animals are in a highly fed and plethoric condition. In the case of cattle, it is often called popularly blood-striking; and in the case of sheep, it is often popularly called blood. In both cattle and hogs, the premonitory or early symptoms are generally so slight as to escape observation, and the apparent commencement of the disease is both very sudden and exceedingly violent; and in all animals whatever, just as in the horse, the grand remedies are prompt and copious bleeding, and judiciously conducted purging. In the case of cattle, Youatt says, "If there is time to do anything, the beast should be bled, and as much blood should be taken away as can be got. A pound and a half of Epsom salts should next be given, and without any carminative; and this followed up with doses of half a pound until the physic operates; its action should afterwards be maintained by six-ounce doses of sulphur every morning. The congestion of blood in the vessels of the brain being removed, and also the congestion which, to a certain degree, prevails everywhere, the beast should be slaughtered; for he is liable to a return of the complaint from causes which would not, previous to his first attack, have in the slightest degree affected him." In the case of sheep, Mr. Cleeve says, "This disease generally occurs when on the road to market. The sheep are then in high condition, and often overdriven beneath a sultry sun. The drover should carefully watch any sheep that lags behind. If it appears stupid and unconscious, heedless of the dog and forgetful of its companions, it should be instantly and copiously bleed from the neck. A prompt flow of blood is indispensable in this case. Every surgeon knows that the loss of the same quantity of

blood taken away in three minutes will have much greater effect than will be produced if it is allowed to dribble away in twice the time. If the sheep is on the road to the butcher, nothing further is necessary; but, should it be attacked at home, the shepherd must change its pasture, and keep the bowels freely open by repeated doses of Epsom salts."

STAGNANT-WATER. Water which has accumulated on land from rain or snow or drainage, and which cannot find a vent, but lies on the surface till it is dissipated by evaporation. It always contains more or less of dead and decomposing organic matter, which has been washed or absorbed into it in the course of its accumulation; and, in some instances, it is so full of this as to emit very offensive effluvia, and send off gases of highly noxious action on the health of man and of all domesticated animals. The nature and effects of it on bogs, marshes, and retentive arable lands are noticed in the articles Bog, Marsh, and Draining. Ponds of it in the vicinity of human dwellings, especially in situations which catch the drainings of yards or of dunghills, are exceedingly pestiferous, and ought never to be allowed. Some kinds of it, particularly steeps of flax and hemp, fetid ponds, farm-yard drainings, and foul ditches, are very fertilizing, and may be usefully employed in saturating dung-heaps, and making earthy composts.

STAKE. An upright piece of wood, fastened in the ground.

STALING. See Urine, Redwater, and Diabetes.

STALK. A stem of a plant.

STALL. The compartment for a horse in a stable, for a cow in a cow-house, or for an ox in a feeding-house. See the articles Stable, Cow-House, and Ox-Stalls.

STALL-FEEDING. The confining of cattle wholly to stalls during the processes of ulterior feeding and of fattening. The peculiar advantages of it, additional to those of soiling, consist in keeping the animals quiet, in nicely adapting their food to their circumstances, and in accelerating the grand result of fitness for the market. See the articles Soiling, Feeding of Animals, and Fattening of Animals.

STALLION. See Horse.

STAMENS. The fecundating organs of plants. They perform functions which Linnæus fancied to be analogous to those of males in animals, and were therefore treated by him as chief characters in framing his artificial system of botany. See the article Botany. They are always present in flowers, as well in those which have no corolla as in those which have; and when a corolla is present, they are always situated immediately within it, and generally alternate with its segments. Each consists of a filament and an anther; and produces in the latter the fecundating dust. See the articles Anther and Pollen. Those of the same flower sometimes cohere by the filaments,—and, if in one set, are called monadelphous,—if in two sets, diadelphous,—and if in more than two sets, polyadelphous. They sometimes also, as in the nineteenth class of the Linnæan system, cohere by the anthers; and they are then said to be syngenesious.

STAMWOOD. The grubbed up roots of felled trees.

STANDARD. A young tree reserved at the felling of a wood; also, a fruit-tree growing in an open exposure, or apart from any wall or trellis, and allowed to assume its natural shape instead of being contorted by pruning and training. A young standard fruit-tree, in general, should not exceed two years from the bud or graft when it is planted, and should be fortified by a stake till it acquire sufficient strength to make a firm resistance to the strongest wind by which it is likely to be assailed.

STANHOPEA. A genus of ornamental, tropical, epiphytous plants, of the orchis family. It is one of the most natural and interesting of the orchidaceous genera; it has one leaf to each pseudo-bulb, and sends out the flowers from the bulb's base; and it comprises a number of species of great beauty and brilliance.

All the species require to become firmly rooted, and must therefore be grown in peaty soil of the most fibrous nature, so that no water may lodge about the roots to cause any of the radicles to rot; and, whenever fine specimens are desired, they must be placed either in pots with an elevation of about a foot above the rim or in large baskets,—for all push their flowers downwards, and cannot possibly make a good show unless placed either high above the pots or in sufficiently capacious and open baskets. Every pot should be filled with large potsherds to within about two inches of the top; the mound above its rim should be built as nearly as possible of the same width as the pot; the heathy portion of the peat should be laid immediately over the potsherds; and the rest of the peat may be either cut or torn into small portions for building the mound, and may be fastened on with a few pegs. Every basket should be formed of oak billets, each about one inch in diameter, and should be open all round and below with distances of two inches between the bars, and should have a depth of about three inches. The plants must be kept in the same pots or baskets without shifting for several years; and, whenever a shift becomes necessary, they must be removed and repotted in the growing season, about the end of July or beginning of August. Most of them, as soon as they have done flowering, commence growing; and from the time of their beginning to show signs of growth till they complete their pseudo-bulbs, they should have great heat and abundant moisture; and then they should be taken out of the moist house and kept in the dry one till they show flower, when they must be taken back to the moist house, and receive

little or no water till they begin to grow. The air in the moist house should be kept up to near the point of saturation, and will be rather injured than benefited by the free or frequent admission of fresh air from without.

The large-flowered stanhopea, *S. grandiflora*, was the earliest introduced into Britain; and is a native of the trees of Brazil. It grows and flowers at the same time, and requires less rest than any of the other species; so that it may be always kept in the moist house. Its flowers are white, and have a peculiar odour, not unlike that of rhubarb. — The ivory-lipped stanhopea, *S. eburnea*, is only a variety of the large-flowered, and not a very marked one.—The graceful stanhopea, *S. venusta*, is a beautiful and very distinct species, and a native of Mexico. Its flowers are similar in form to those of the large-flowered, and also emit a strong odour like that of rhubarb, but have a yellow colour. This species requires a good rest after it has done growing.—The four-horned stanhopea, *S. quadricornis*, is a well marked species, having four horns on the lip. It is not so rich in colour as some of the others, but has a more delicate scent than many. It flowers earlier than either of the former, and of course grows sooner.—The bagged stanhopea, *S. saccata*, is a most interesting species, a native of Mexico, having a large bag at the base of the lip. It has an orange lip with straw coloured vessels, and petals beautifully covered with dark spots. It flowers in May and June, and sometimes later. —Ward's stanhopea, *S. Wardii*, is a very handsome species. It has flowers of a pale yellow, beautifully spotted, and is well worthy of the cultivator's attention. It flowers in June and July, and very seldom begins to grow before August. The number of flowers on a spike is from five to twelve.—The tiger-marked stanhopea, *S. tigrini*, is the most splendid and singularly formed species of all the genus. The lip is dark and of a very fleshy texture; and the vessels and petals are of a pale colour, with large dark stripes. It flowers in June and July, and begins to grow in August; and it has from two to three flowers on a spike.—The Martian stanhopea, *S. Martiana*, is very nearly related to the tiger-marked.—The eyed stanhopea, *S. oculata*, is a pleasing and very interesting species. The lower portion of the lip has a yellow cast, and has a dark spot resembling an eye; and the upper portion is like white ivory, and beautifully spotted with purple. The vessels and petals are of a pale straw colour, finely spotted with dark purple.—The Devonshire stanhopea, *S. Devoniensis*, is a very splendid species, somewhat like the tiger-marked, but not so large, and has a very differently formed lip, and the vessels and petals of a much darker colour. It comes into flower in June and July.—The remarkable stanhopea, *S. insignis*, is another beautiful species. The vessels and petals are pale yellow, with purple spots; and the lip is very curiously formed, and of a thick and fleshy nature.

STANLEYA. A small genus of ornamental exotic plants, of the cruciferous order. The pinnatifid species, *S. pinnatifida*, is a frame, perennial rooted herb, of about a foot in height, carrying yellow flowers in June and July; and was introduced to Britain about 30 years ago from Louisiana; and is propagated from seeds.

STAPELIA. A genus of curious, Cape-of-Good-Hope, evergreen undershrubs, of the swallow-wort family. A number of species which formerly belonged to it are now distributed among twelve other genera; but nearly forty, still belonging to it, occur in British collections. Their stems are short and fleshy, and supply the place of leaves, and vary in height from 3 to 25 inches; and their flowers have a remarkable complex organization, and are distinguished by strange colouring and spotting, and emit an offensive fetor, and, in a number of instances, bloom in autumn or in winter. All love a soil of sandy loam, and are propagated from cuttings.

STAPHISAGRIA. See Larkspur.

STAPHYLEA. See Bladder-Nut.

STAR-APPLE, — botanically *Chrysophyllum*. A genus of tropical, evergreen, ornamental fruit-trees, of the sapota tribe. Six species, varying in natural height from 15 to 100 feet, and all, with one exception, carrying white-coloured flowers, have been introduced to Britain, principally from the West Indies and tropical America; and nine more are known. The leaves are deep green above, and shine like satin below, and cause the plants to have a fine appearance in the stove throughout the year; the fruit is at first rough and astringent, but becomes mellow with age and keeping, and is much relished in the native countries of the plants; and the timber of the larger species is used in carpentry and for shingles to cover houses. All the introduced species love a soil of rich mould, and are propagated from cuttings. The best known of them, comprising several varieties, is noticed in the article Cainito.

STARCH. A well known and very abundant proximate principle of plants. It constitutes a large portion of esculent seeds, and is very common in fleshy roots, and abounds in the pith of some ligneous stems, and occurs in the cellular tissue of even such plants as burdock, buttercup, dropwort, deadly night-shade, white bryony, bistort, and henbane. It passes into sugar during the germination of seeds, and plays an important part in the chemistry of all the subsequent growth of plants, and forms a bulky and important ingredient in the ripened state of their esculent products for the nutrition of man and of the lower animals. In a separate and manufactured state, also, it is nearly identical with arrow-root, cassava, and salep, and constitutes the chief bulk of sago, tapioca, farina, sowens, and potato tubers. See the articles Nutrition, Germination, Seed, Alimentary Principles, Amy-

LINE, ARROW-ROOT, CASSAVA, ORCHIS, SAGO, FARINA, OATMEAL, and POTATO.

"Starch," says Boussingault, "is contained in the cells of vegetables under the form of small white granules which have no crystalline structure. In the year 1716, Leuwenhoeck ascertained that these granules were globular bodies more or less regular in their contours. He believed that he could perceive each globule enclosed in an envelope, a kind of sac, different in its nature from the matter which it contained. M. Raspail, a few years ago, confirmed by his own researches the observations of Leuwenhoeck; he further attempted to measure the diameter of the globules in different kinds of starch, and came to the conclusion that their capsule is insoluble, and that it is the internal part alone which is soluble in hot water. Since then MM. Payen and Persoz have ascertained that if the globules of starch be really surrounded by a capsule, it must be present in a quantity scarcely appreciable,—a quantity not exceeding $\frac{1}{4000}$th of the weight of the starch. These first researches were followed by the subsequent observations of M. Payen, who has devoted himself to the study of the amylaceous principle with a zeal and perseverance which must secure him the gratitude of chemists and physiologists. M. Payen has examined a vast number of feculæ microscopically; the largest granules he observed were obtained from one of the varieties of potato, from the *Menispermum palmatum*, and the *Canna gigantea*. The globules of starch frequently exhibit a polyhedral appearance, a figure which evidently results from their mutual pressure as they have lain in the cells of the vegetable. Notwithstanding a great general analogy of form, the granules of the starch of different species of vegetables, still present peculiar physiognomies, so that they can be distinguished in many instances by the practised eye. A character common to the majority of feculæ, however, is roundness of contour, when their particles have not been compressed by their contact in contiguous cells. Microscopical and chemical researches alike show that starch is homogeneous in properties, as in composition; that its globules are composed of concentric layers, the external of which have exactly the same characters as the internal layers.

"In the natural state, starch is insoluble in water and in alcohol; it is very ductile; and under the influence of certain agents, it exhibits a great degree of contractility. Feculas retain water with considerable force; the quantity retained varies with the temperature at which the drying was accomplished. Thus the fecula of the potato, which is moist and porous, even when subjected to strong pressure, still retains 45 per cent. of water. This is the green or raw starch of manufacturers. Dry starch is very hygrometric. If after being dried it is placed in an atmosphere saturated with moisture, at 20° centig. (68° Fahr.) it will absorb nearly 36 per cent. of water, and its bulk increases in the ratio of one to one and a half; in this state starch is brilliantly white, and its grains adhere so closely that they form a mass of sufficient firmness to take the impress of a seal. Starch in this state, however, pressed upon paper yields no perceptible trace of moisture; it is too hard and adherent to pass through a sieve; and when thrown on a metal plate heated to 257° Fahr. its particles immediately unite and form a cake. The starch of commerce, in the state in which it is usually found in shops, contains 18 per cent. of water; it is either pulverulent or readily reducible to powder, though by slight pressure in the hand, it may be formed into a mass or ball. After drying in vacuo at the ordinary temperature, starch retains no more than 10 per cent. of moisture; a temperature not less than 284° Fahr. is required to dry it completely; the water which it retains at this temperature belongs to its constitution, and cannot be taken from it except by combining it with bases. MM. Collin and Gaultier de Claubry discovered the important character of starch, that of yielding a fine blue or violet colour on combining with iodine. According to M. Payen, the colour is more intense, nearer to blue and more lasting, in proportion as the starch is more strongly compressed; the effect of separation is to turn the blue to shades of violet which approach redness as the substance is looser. The same fecula, according to the degree of its aggregation in plants, is seen to assume shades, which are first reddish, then violet, and eventually of a more decided blue colour, under the action of iodine. M. Lassaigne has noticed a very curious property of the combination of iodine and starch; if an amylaceous fluid, having the decided blue colour, be heated to 193° or 194° Fahr., the solution becomes completely blanched; but it resumes its former tint as the liquid cools. This property, which starch possesses of striking a blue colour with iodine, renders one of these bodies an excellent test for the other. However, as the iodine must exist in the free state to produce its effect, it is necessary, when the blue colour does not show itself at once, in a solution in which iodine is suspected, and to which starch has been added, to add a few drops of sulphuric acid, so as to decompose the hydriodic acid in cases where it may exist.

"It is familiarly known that, if raw starch be mixed with boiling water, the result will be a thick, paste-made starch. According to M. Payen, the change that takes place in the state of the fecula is owing to a swelling, a rupture, or disgregation of its granules. By heating a drachm of starch, mixed with about a couple of ounces of water to about 140° Fahr., the microscope shows us that the smallest or youngest grains,—those possessed of the least cohesion,—have absorbed a considerable quantity of water, and that the expansion of the contents has caused a certain num-

ber of the globules to burst. At this temperature, however, some grains of fecula are observed, which do not appear to have yet attained their maximum of enlargement, and whose contents consequently are not yet diffused through the liquid. It is only between 161·6° and 212° Fahr. that the maximum of expansion becomes general and that the solution acquires its greatest consistency. The remarkable property possessed by starch of making a glutinous solution or thick paste with water under the influence of heat, led M. Payen to conjecture that a contrary effect would be produced by lowering the temperature,—that the starch might be recovered in its original state of distinct globules by suitable management; and this he in fact accomplished by an ingenious procedure. Starch appears to suffer no actual change when diffused in water by exposure to a temperature of 212° Fahr.; the granules have only swollen to about thirty times their original dimensions by the imbibition of a large quantity of water.

"Formerly, the starch of commerce was universally obtained from grain,—wheat; at present, the potato furnishes a still larger quantity than grain. In the equatorial regions of South America, starch is abundantly prepared from the *Jatropha manihot*, and from several species of palm. To obtain starch from wheat, the grain is either coarsely ground and mixed with water in large tubs, or it is put to steep in sacks until it is so soft that a process of kneading suffices to set the starch at liberty. To obtain it from potatoes, the tubers are grated after having been well washed, and the pulp being thrown on a sieve, the starch is carried off by the water and deposited in suitable vessels. The washings in the manufacture of potato starch soon become putrid by reason of the azotised matter which they contain, and until lately occasioned much annoyance, until M. Dailly conceived the happy idea of turning them to account as liquid manure. None of the amylaceous principles or feculas obtained by the ordinary processes are absolutely pure; even supposing all the soluble substances to have been removed by washing, they still retain fatty matters, azotised principles, and colouring substances. Starch is purified by following up the water washings by the action of alcohol, of acetic acid, and of ammonia. Starch in its state of greatest purity, and dried at 212° Fahr. contains, according to the analysis of M. Jacquelain, 44·9 per cent. of carbon, 6·3 of hydrogen, and 48·8 of oxygen.

"By slight roasting, amylaceous feculas undergo considerable changes; they become soluble in water, and then present the properties of gum. Starch thus roasted, supplies the place of gum in various manufacturing processes; still it should not be confounded with gum in a chemical point of view. The acids act with more or less energy on starch, and give rise to different products. Nitric acid, when it is diluted with water, merely dissolves fecula; but at a certain degree of concentration, it exerts a destructive action. In this reaction several acids are formed, among others oxalic acid. By employing very dilute sulphuric acid, Kirchhoff succeeded in changing starch into a saccharine substance similar to the sugar of the grape. The operation may be performed in a leaden or silver pan, or, what is preferable, especially when the process is carried on upon the great scale, in wooden vessels, in which the liquid mass is heated by steam. According to M. Couverchel, several organic acids are capable of changing fecula into sugar in a similar manner; such are oxalic, tartaric, and malic acids. The artificial conversion of starch into grape sugar has not yet been satisfactorily accounted for. The acid employed does not seem to undergo any change; it is found in its original state and quantity after the operation. M. de Saussure thinks that the effect of the reaction is the fixation of water; thus 100 parts of fecula yielded him 110·40 parts of sugar. M. Couverchel and M. Guérin, on the contrary, state that the quantity of sugar obtained was less than that of the starch they employed. Gluten exerts a reaction on starch similar to that produced by acids; Kirchhoff discovered, that under the influence of the azotised matters which are met with in flour, the fecula is converted into sugar. Two parts of starch being mixed with four parts of cold water, on adding twenty parts of boiling water, a thick paste is produced; if into this one part of dry, powdered gluten be introduced, and the mixture be kept at the temperature of 140° Fahr., the paste becomes more and more liquid, so that the mixture may be filtered at the end of from six to eight hours. By concentration a syrup is obtained, in which small crystals of sugar are perceived. It is well known that during the act of germination, fermentable saccharine matter is produced. Kirchhoff concluded from his experiments, that this production of sugar in germination is attributable to the reaction of the gluten on the starch. Germinating grain, barley-malt for instance, reacts rapidly and powerfully on any fecula with which it is brought into contact,—a fact well known to, and constantly taken advantage of, by manufacturers of spirits from potatoes and raw grain, large mashes of which are rapidly converted into sweet fermentable liquids under the action of a little malt. These facts, it is evident, cannot be explained by Kirchhoff's experiment; in the fermentation of the potato, the mass of fecula to be converted into sugar is too great compared with the quantity of gluten which exists in the malted barley. Further, the gluten in grain which has not germinated, scarcely exerts any appreciable action. The principle which, in the preceding operations, converts the starch into sugar must therefore become developed during germination. This important point in the art of the distiller has

been investigated with great ingenuity by M. Dubrunfaut; and MM. Persoz and Payen succeeded in separating the peculiar matter in barley malt which possesses the property of converting starch into sugar. This matter has been called diastase.

"Diastase exists in the seeds of all the cereals which have germinated; it is met with more especially near the germs, it seems even that the radicles contain none of it. Nor is diastase observed in the shoots or roots of the potato; it is to be met with only in the tubers, around the eyes or points where the young sprouts are developed, precisely as M. Payen has remarked, in the place where we should conceive its presence to be necessary for effecting the solution of the fecula. It is also found to exist in the bark and beneath the buds of trees, always in contact with starch. Diastase is generally obtained from malt; and when carefully prepared, its peculiar power is such, that one part by weight is sufficient completely to liquefy two thousand parts of starch. Diastase is solid, white, amorphous, insoluble in pure alcohol, soluble in water and weak alcohol. The solution very readily undergoes change; it becomes acid, and then no longer exerts any action on fecula. When dried, it keeps much better; still, at the end of two years, it seems to have lost its distinguishing properties. Diastase has no action on vegetable tinctures, on albumen, gluten, cane-sugar, gum-arabic, or the woody-fibre. That which more especially characterizes it, is its powerful action on fecula; it may be advantageously used to separate and purify the preceding substances, when they are mixed with starch. The presence of diastase in malt explains the phenomenon of the liquefaction of starch effected by the action of a small quantity of that substance. This solution is not effected by gluten, nor by hordein, as M. Dubrunfaut had imagined. By the action of diastase, or of malted barley, the starch on being liquefied is not entirely converted into sugar; there are other distinct products to be considered in this change. The syrup obtained by concentrating the liquefied starch, contains sugar capable of undergoing the vinous fermentation, and a gummy matter, dextrine. These two substances may be separated by means of dilute alcohol, which dissolves the sugar and leaves the gum untouched. The relative quantities of dextrine and sugar produced by the action of diastase are variable, and depend both on the temperature at which the process is conducted, and on the continuance of the reaction. In the first period of the process, the dextrine predominates; but it becomes less and less by degrees, and finally gives place to sugar. M. Guérin ascertained a curious fact, which shows how the diastase developed in plants may act on their starch: reaction takes place even at ordinary temperatures. In one of M. Guérin's experiments, at a temperature no higher than 68° Fahr., a quantity of starch, at the end of 24 hours, was converted into syrup, which yielded 77 per cent. of saccharine matter.

"M. Payen freed dextrine from the sugar which usually accompanies it by precipitating a syrup of fecula previously dissolved in dilute alcohol, by means of alcohol nearly free from water. Dextrine well dried, and reduced to powder, has a specific gravity of 1·51. The specific gravity of pure starch is 1·51; that of the sugar of starch 1·61. M. Payen found dextrine dried at a temperature of 212° Fahr. to consist of 44·3 per cent. of carbon, 6 of hydrogen, and 49·7 of oxygen,—a composition identical with that of starch. We have seen that water, acidulated with sulphuric acid, transforms starch into sugar; and that in this respect, the acid acts precisely in the same way as malted barley, like which, the acid first causes the fecula to pass into the state of dextrine. By checking the reaction at the proper moment, this substance may thus be obtained, as was shown by Messrs. Biot and Persoz. When starch, for instance, is triturated with concentrated sulphuric acid, if the mixture be diluted with half its volume of water, and be left at rest for an hour, alcohol will throw down almost the whole of the starch employed in the state of dextrine.

"M. Payen has remarked that starch is never met with in the vegetable tissues whilst in the rudimentary state; the spongioles, the radicles, the foliaceous buds, the interior of the ovules contain none of it. Nor is starch found in the epidermis, nor in the primary cells of the subjacent tissues. This proximate principle seems to be excluded from those parts of vegetables that are more directly exposed to atmospheric influences: it is only met at a certain depth; and the globules which constitute starch increase in number and in size in the cells most remote from the surface. The subterraneous organs of plants, —certain bulbs, most tubers,—abound in amylaceous matter. It might be maintained that light modified this substance, at the very moment that it was subjected to the vital influence, and that it was only preserved in the dark. On the globules of some species of fecula, there is found a point or hilum, which, according to some observers, serves to fix them to the parietes of the cells which enclose them. It often happens, however, that no hilum can be distinguished, even by the help of the most powerful microscopes; to render it apparent, recourse must be had to desiccation, which, by causing the globular mass to shrink, allows the part carrying the hilum, to project, by reason of its stronger cohesion. M. Payen does not regard the hilum as a point of permanent attachment, connecting the grain of starch to the interior wall of the cell. He considers it as the orifice of the duct by which growth is effected through intersusception. In support of this view, M. Payen observes, that in a great number of vegetable cells, especially in those of the potato, and of the rhizomas, the

globules of starch are developed in such quantity, that it is actually impossible that each of these should be united directly to the inner wall of the cell."

The starch of commerce is extensively used in medicine, in the stiffening of linens, and in various arts. The best of British manufacture from wheat exists in small columnar masses, and is insipid, inodorous, white, soft, friable, and easily broken into powder. The wheat used in making it is either entire or coarsely bruised; and is steeped in cold water till it swells and yields by pressure a milky juice; and it is then subjected to pressure in coarse bags placed in vats filled with water. When all the milky juice is expressed, the bags are removed, the fecula gradually subsides to the bottom, and the supernatant liquid soon ferments, and suffers a resolution of the principles dissolved in it into alcohol and acetic acid. The whole, after fermentation, is poured into tubs called frames; and, after the fecula subsides in these, the supernatant liquid is poured off,—the upper part of the sediment, being dirty and discoloured, is scraped off,—and the rest of the sediment, constituting the main bulk and purest portion of the fecula, is repeatedly well washed, pressed in cloths, and dried by a gentle heat; and during the process of drying, it so contracts as to form itself into the somewhat regular, small, six-sided columns in which it is sold in the shops.—As aliment to the sick and the feeble, or as food to the healthy and the strong, it is far less suitable in this separated and comparatively pure state, than in the modified forms of arrow-root, tapioca, sago, and gruel; but as a demulcent in the way of enema, it serves admirably in its separated form, for either man or beast; and it is used, in both human and veterinary medicine, for alleviating the acrid action of bile in bilious diarrhœa and dysentery, and for sheathing the rectum in cases of abrasion and inflammation of the gut.

STARLING. A genus of passerinous birds, intermediate in character between the sparrow group and the crow group. The common species, *Sturnus vulgaris*, is a plentiful native of Britain, and abounds throughout a large portion of Continental Europe. It flies in large and crowded flocks; and feeds on larvæ, insects, worms, and molluscs; and is of service to cattle by relieving them from the attacks of insects. It is a beautiful bird in both shape and plumage; and can be easily tamed; and may be taught to sing, and even to speak; and is a great favourite with most kinds of bird-fanciers. The total length of the adult male is 8½ inches; the plumage is nearly black, with reflections of green and violet, and with spottings of white or fawn-colour; and the legs are dark reddish brown. The young male, however, has brown grey plumage. The nest is built in church-steeples, under the eaves of houses, in crevices and holes of lofty walls, in rents and openings of ruinous towers, in cracks and fissures of sea-cliffs, and sometimes in pigeon-houses and in hollow trees; and it consists of straw, roots, and dry grass. The eggs amount to four or five, and are each one inch two lines long, ten lines broad, and of an uniform, delicate, pale blue colour.

STAR OF BETHLEHEM. See Ornithogalum.

STAR OF THE EARTH. See Plantain.

STAR-THISTLE,—botanically *Centaurea Calcitrapa*. An ornamental, annual, indigenous plant of the gravelly soils of England. It has a height of about a foot, and carries pink flowers in July and August. It constitutes the type of a subgenus of the centaureas; and is distinguished from all the other species, except those of this subgenus, by the spinosely pinnate structure of its calyx. One frame perennial-rooted species, with white flowers, one hardy biennial species with purple flowers, and five hardy annual species with yellow flowers, all belonging to the subgenus, and therefore sharing the name of star-thistles, have been introduced to the gardens of Britain from Southern Europe, Northern Africa, and the Levant.

STARWORT. See Aster.

STARWORT (Water). See Callitriche.

STATICE. A genus of ornamental plants, of the plumbago tribe. Four species grow wild in Britain; about sixty have been introduced from other countries; and a number more are known. About twenty species which formerly ranked as statices, comprising sea-pink and the other kinds called thrifts, now constitute the genus armeria. The indigenous statices are popularly called sea lavenders; a few of the introduced species are either annuals, biennials, or evergreen undershrubs; and most of the others are evergreen herbs, either quite hardy or requiring only the protection of a frame, and principally carrying blue flowers, in summer, at the height of from 6 to 15 inches.

The common sea-lavender, or marsh wild beet, *Statice limonium*, is an abundant, evergreen, herbaceous indigen of the muddy sea-shores and marshy estuaries and river-mouths of England. Its root is woody, thick, tough, reddish, and astringent, and sends out many strong fibres, which strike deep into the ground; its leaves rise from the root-crown, and are ovate-lanceolate, smooth, leathery, glaucous, and from two to five inches long; its stem is naked, and rises upwards of a foot high, and divides into many branches, which again divide into smaller branches toward the top; and its flowers grow in slender spikes on the extremities of the sub-branches, and are ranged above one another on one side of the stalk, and come out of narrow covers like sheaths, and have a fine blue colour, and bloom from May till August, and are succeeded by oblong seeds.—The netted sea-lavender, *Statice reticulata*, is an evergreen herbaceous indigen of similar situations to the preceding, but is far less abundant, and occurs chiefly on the eastern shores.

Its leaves are lanceolate and about 3 inches long, and lessen gradually to both ends; its stem is 4 or 5 inches high, and divides into many spreading branches; and its flowers grow on short spikes, and profusely cover the branches, and have a whitish blue colour, and bloom in July and August.—The two-nerved sea-lavender, *Statice binervosa*, is an evergreen herbaceous indigen of the chalky cliffs of England, about a foot high, and carrying blue flowers from June till September, but is rare.—The dwarf sea-lavender, *Statice nana*, is also a rare, evergreen, herbaceous, blue-flowered indigen, but has a height of only about 3 inches.

The broad-leaved sea-lavender, *Statice macrophylla*, was introduced to Britain a few years ago from Madeira, and is one of the largest and most showy of the exotic species. It is a very desirable greenhouse plant, and has rapidly come into great celebrity; but, even in a greenhouse, is impatient of the occasional rigours of our climate when forming its young leaves late in autumn. The leaves are large, obtuse, and spathulate, and taper at the base, and sit closely round the erect shrubby stem, and constitute a dense, handsome, tufty mass of foliage; the flower-stem forms a large branching panicle, two or three feet high, with branches and peduncles of a flattened shape and broadest upwards; and the flowers are borne in an aggregated position on the ulterior ramifications of the branches,—each with a flat, spreading, rich purple blue calyx, which unfolds five white and somewhat fugitive petals, but remains itself on the plant for months.

STAVESACRE. See Larkspur.

STEADING. See Farm-Buildings.

STEAM. The hot elastic vapour of water. A notice of its many economical uses, and of the mighty achievements which have been effected by it in modern times as a motive power, and of the vast accessions of convenience and produce and wealth which it now brings to man in traffic and manufacture, would possess surpassing interest, but does not belong to the design of our work. Its principal actual uses hitherto, in matters connected with the garden and the farm, are the heating of hothouses, the cooking of food for cattle, and the driving of the machinery of the farmery; and its principal prospective use, in connexion with the cultivation of the soil, is the impelling of implements for ordinary field tillage, for subsoil-ploughing, and for the breaking up of bogs and other waste lands. See the articles Hothouse, Steam-Engine, Steaming-Apparatus, and Steam-Ploughing. "That the steam-engine," said the author of four papers on the application of steam to the purposes of husbandry, published about thirteen years ago in the Quarterly Journal of Agriculture, and designed to evoke general interest in the experiments which were then a-foot in steam-ploughing,—"That the steam-engine would, at no very distant day, supply the place of animal labour in agriculture, and become as mighty an instrument in augmenting the productiveness of the soils, as it has proved in creating and economizing manufactures, in navigating the ocean, and in travelling on land, was many years ago predicted by Franklin,—a prediction reiterated by Davy, and latterly acknowledged and enforced by many distinguished agriculturists. The successful application of Mr. Heathcoat's invention to the culture of bogs,—the most repellant and obstinate of waste land,—leaves no doubt of its applicability to soil already in cultivation. Coals are now procurable throughout Great Britain, at prices which have caused the steam-engine to be extensively introduced as a substitute for animal labour in many of the processes connected with husbandry. Thrashing, cleaning, and grinding corn, hay-chopping, turnip-slicing, &c., are now performed by small engines fixed on farm premises. Even the churn has its steam-engine managed by the dairy maid; and so great is the advantage arising to the dairy farmer, from the regularity of motion, and economy produced by it, that hundreds of small engines for this familiar purpose alone, are used in the North of England and in Scotland. But these are humble savings compared with the benefit to be derived from the vast steam power which may be brought to bear on the soil itself. Those agriculturists who are acquainted with the effects produced by the valuable sub-soil plough recently invented by Mr. Smith of Deanston, will readily appreciate the importance of an invention which will enable him to employ that kind of plough at a much diminished cost per acre. Mr. Smith's plough with steam power, will effect a revolution in agriculture. Implements of husbandry have hitherto been restricted in form, weight, and dimensions, to the powers and manageableness of a team of horses. A new class of instruments will take their place; the stiffest soils may be broken up and pulverized to any desired depth; strong clays, the natural wheat lands, may be profitably cultivated, rendered more fertile, and fitted to bear a better and more systematic rotation of crops."

STEAM ENGINE. The use of fixed steam engines, of from four to eight horse power for impelling thashing machines, is now common on large farms in the north of England and the south of Scotland; and the use of both fixed and portable steam engines, of two, three, and four horse power, for impelling the several machines of the farmery, is pretty general in many of the best parts of the centre and south of England. Steam power, next to water-power, is the most desirable for the thrashing machine; and, in consequence of both its greatness and its steadiness, it affords scope for the construction of the machine being of the most admirable description. See the article Thrashing. A non-condensing fixed engine is the most simple, and at its first

cost the most economical; but a condensing one, notwithstanding its greater expense, is the most desirable. A fixed engine, whenever its power can be made fully and generally available for the uses of the farmery, is more profitable than a portable one; for when a convenient building containing the chaff-cutter, the turnip-slicer, the corn-crusher, the cake-crusher, the bone mill, the flower mill, the cider mill, and other useful machines immediately adjoins the barn, all, as well as the thrashing-machine, can be conveniently driven by the engine, and the apparatus for steaming and cooking can at the same time receive its full supply of steam from the boiler; and the fixed engine, besides being very much cheaper at first than the portable one, is ever after more easily kept clean, and managed with less trouble. Yet when the machines to be impelled cannot be kept around one spot, a portable engine is exceedingly convenient and of great practical value; and may be obtained from the manufacturers completely mounted on a carriage with wheels and shafts, for easy removal, with one horse or two according to the size, from place to place in the same manner as carts or waggons. Dean of Birmingham's four-horse power portable steam-engine is very simple, safe, efficient, and durable, and excellently adapted for agricultural purposes. It may be styled a double engine, being mounted with two steam cylinders, thereby dispensing with the heavy fly wheel, and rendering it much more portable, and easily drawn by two horses. Its power is sufficient for driving several of the smaller machines of the farmery, such as chaff cutters, corn cutters, turnip cutters, cake breakers, and bone mills, at the same time; and when employed in thrashing, with an adequate machine, it will be found equal to six or eight horses. Its price is £140; and the working parts of it may be enclosed in iron, at an extra charge of £5. Dean's two horse power portable steam-engine will be found to answer the purposes of many farmers fully as well as one of greater power, being equal to the performance of much more work in cutting chaff and turnips, bruising corn, grinding, &c., than is required to be done upon farms of moderate extent; and when employed in thrashing, it has been declared by many farmers to be equal to four horses. It is more portable than engines of larger power, and is drawn with ease by one horse. Its price is £80. Dean's three horse power portable steam-engine, is also an exceedingly useful farmer's engine, and calculated to drive the usual four horse thrashing machines to much greater advantage than by animal power. Its price is £110. These steam engines being simple, and free from complicated movements, are easily managed and not liable to get out of order. They are fitted with superior metallic pistons, thus obviating the trouble and risk of packing, and with metal side valves in lieu of steam taps; and they will be found much more durable and efficient than engines with vibrating or oscillating cylinders.

STEAMING APPARATUS. The advantages of cooking the food of horses and cattle and pigs, —in small quantities by boiling, and in large quantities by steaming,—are noticed in the articles Boiling, Food, Feeding of Animals, Horse, and Hog. A common apparatus with open boiler to steam food for from ten to twenty horses, may consist of a cast-iron boiler of 40 or 50 gallons in capacity, a sheet-iron steaming-pan of corresponding capacity, an ordinary furnace similar to that of a washing-house, and a crane for lifting off the steaming-pan. The boiler has a double edge or lip, forming a groove about 2 inches deep and 1½ inch wide, running quite round the mouth; and it is set on the furnace. The steaming-pan has a bottom like a large-meshed sieve, fixed into it at about 1½ or 2 inches from its lower edge; it is furnished with an iron bow, attached to gudgeons placed a little below the line of the centre of gravity of the vessel, so that it may be easily overturned when suspended by the bow, for the convenience of emptying it, and is retained in the upright position by a catch; and it has a close cover of wood or of sheet-iron. In using the apparatus, both the boiler and its groove are filled with water; and the steaming-pan is then placed on the top of the boiler, its lower edge falling into the groove, the contained water forming a hydraulic lock or seal, preventing the escape of steam, at a pressure a little above that of the atmosphere. The furnace being kindled, the water in the boiler soon produces steam, which, rising into the upper vessel, pervades every part of it, and being continued for a sufficient length of time, produces the desired effect. This in the case of potatoes will require from 30 to 48 minutes. The crane is worked in the usual manner, and by means of a rope or chain, a man can remove the pan with its contents; and, while thus suspended, the catch of the bow being disengaged, the contents are discharged into a trough prepared to receive them. One advantage of this kind of apparatus is, that the boiler being open, can be applied to the purpose of boiling grain or other substances, or for any purpose in which hot water may be required.

Some close-boiler apparatuses for steaming have hemispherical boilers of cast-iron; and others have malleable iron boilers of the common waggon shape. The latter, though a little more expensive in the first cost, are, in many places, the most economical for fuel; and hence their adoption may be regulated by the price of fuel in the localities where they are to be used. The steaming vessels may be varied to suit situation and circumstances; and may be either chests of deal, chests of sheet-iron, or casks; the last in most cases will be found the most suitable. The other auxiliary apparatus, as steam-pipes, water-cistern, valves, stop-cocks, &c. may be adopted of such materials as shall be most conveniently pro-

cured; and if a special water-cistern be not used, the boiler must be filled through a funnel and stop-cock at each operation. The furnace may be set either on the right or the left side of the steaming-house, or in the middle of it, according to the position of the chimney; and the steaming vessels may be distributed as the situation requires. A good variety of boiler to steam for from 10 to 16 horses is 3 feet 4 inches long, 18 inches wide, and 21 inches high, and is set lengthwise in a brick furnace; the fire-grate being placed under the front end of the boiler, and a flue carried from that quite round, before entering the chimney. By this arrangement, the fire or heated air is held as long as possible in contact with the boiler, which takes up the greater part of the heat evolved from the burning fuel; and it is worthy of remark, that the effect of the fuel depends much on the proper construction of the furnace and flues, to bring out the greatest effect from a given quantity of coal. The boiler is provided with a man hole, to the door of which the steam-pipe is attached; and both can readily be removed at pleasure. It is also furnished with a safety-valve, which need not be loaded above 2 lbs. to the square inch. A feed-pipe is also attached by a coupling screw to the boiler, and its other extremity to the bottom of the water-cistern, placed at not less than 6 feet above the level of the boiler. One end of a rod is jointed to the projecting end of a lever above the water-cistern; and to the other end of this rod, after passing through a small stuffing-box in the top of the boiler, is attached a stone float, or a hollow copper ball, immersed in the water of the boiler. The opposite end of the lever is connected to the rod of a valve, placed at the bottom of the cistern, closing the entrance to the feed-pipe; and the rods at the two ends of the lever are duly balanced with the float on the one side, and the valve on the other. When the surface of the water in the boiler falls by evaporation, or any other cause, the float losing the support of the water, falls along with it, and opens the valve at the mouth of the feed-pipe, letting a quantity enter until the surface again rises, carrying up the float to its former position, which, through the medium of the lever, shuts the valve, and so cuts off further supply, until a repetition of the operation is required by further evaporation. As an additional security, two gauge-cocks are inserted into the boiler; and these have their inward extremity prolonged downward to such length, that when the boiler is in a proper state, the one terminates in steam, the other in water, so that the one cock, when opened, emits steam, the other water. If too much water is introduced, the steam-cock will blow out water, a part of which may therefore be drawn off; and if the water-cock blow out steam, the water has fallen too low in the boiler, indicating some defect in the action of the feed-pipe, and that a supply should be introduced. For the convenience of drawing off water from the boiler for any purpose, a nozzle is attached to it, by which a supply can be got at any time when the boiler is in operation. The pipe which conveys the steam from the boiler to the steaming vessels may have a swan-neck curvature, and should not be less than 2 inches in the bore, and must send off a branch to each steaming-vessel or receiver. The steaming vessels — if casks are used, which are the most convenient—are suspended by gudgeons between posts, poised in such a manner, as to make them easily overturned, for the purpose of discharging the contents; and each is furnished with a false bottom perforated to admit the steam; while a short nozzle, of about 4 inches long, of 1½ inch pipe, is fitted to the real bottom of the receiver, projecting outwards; and the connection between this and the steam-pipe is formed by means of a piece of copper or tin-plate tube, 6 inches long, which slides externally upon the branch of the steam-pipe,—and when the end of the branch is brought to coincide with the nozzle, in the bottom of the receiver, the sliding piece is pushed forward till it embrace both parts. The size of the casks will be regulated by the quantity required to be done; but the boiler here described will supply steam for three casks of from 30 to 40 gallons each. The covering of the receiver is by no means of importance; a wooden cover, with two or three folds of thick sacking, or an old sack, thrown over it, does quite as well as a steam-tight cover. The true bottom of the casks should be perforated with a few holes, to allow the escape of condensed water, which also carries off the colouring matter of the potatoes. When the operation is concluded, the steam-pipes are disengaged; the ends may be stopped with a wooden plug,—or by the stop-cocks, when such are used; but, at the same time, proper attention must be given to the fire, that the production of steam may be checked. The casks are now overturned, and the contents discharged into a trough, or what is better, into a large close wheel-barrow.—In this kind of apparatus, it is evident that the boiling of any substance cannot be done in the boiler itself; but it is well known that any substance can be boiled in a separate vessel, by introducing steam to it, either directly to the liquid that it contains, or by applying the steam through metallic pipes, or into a vessel surrounding the first. These, however, are attended with considerable expense; as distinct vessels from those for steaming roots, &c. must be employed. It has also been ascertained, though perhaps not generally known, that grain of any kind cannot be dressed or cooked by dry steam applied to the dry grain. If the steam is at a low pressure, or a little above that of atmospheric, a species of parching is produced on the grain so treated; and if steam of very high pressure is applied, the grain may be entirely carbonized.

An intermediate, and very simple process, has, however, been found, whereby grain of any sort can be completely boiled, which is done by soaking the grain in water for a period of from six to twelve hours, according to its state of dryness, and then placing it in the receiver described for steaming roots, and applying steam for an hour; and thus we are provided with a simple and efficient steaming and boiling apparatus, applicable alike to the cooking of juicy roots, or tubers, and dry grains.

Chesterfield's portable steaming apparatus consists of a tripod-mounted, cylindrical, chimney-crowned boiler, a suspended, frustra-conical steaming-pan, and a connecting elbow-pipe between the two; and has in the chimney an opening for the supply of fuel,—on the top of the boiler an opening for the supply of water,—in the lower part of the boiler a tap for drawing off water,—below the boiler an opening of the fire-grate,—and in the lower part of the steaming-pan a pipe for carrying off the pernicious extract of potatoes. This apparatus is both cheap and convenient; and will be found especially beneficial to farmers, butchers, and other feeders of pigs and cattle; and is calculated to supersede in many cases the fixed furnace as it can be removed at pleasure from one part of the homestead, or of the farm, to another; and, from the simplicity of its construction, there is not the least danger of its getting out of order. Another important consideration is the great saving effected in consumption of fuel, as 8 or 10 sacks of potatoes can be steamed with 1 cwt. of coals. The boiler may at any time be used separate from the steamer where a large quantity of hot water is required for any purpose, and may with perfect safety be removed to any place at pleasure.

STEAM-PLOUGHING. Two principal attempts to apply steam-power to ploughing were commenced, about seventeen years ago, by John Heathcoat, Esq., in bog reclamation, and several years later by John Upton of Southwark in general tillage. But we can afford to quote only a general notice of each; and must refer any of our readers who wish a fuller account to the 7th volume of the Quarterly Journal of Agriculture, and the 12th volume of the Transactions of the Highland Society.

"The principal machine in Mr. Heathcoat's invention is locomotive, and so contrived as to be capable of travelling on the surface of bogs, the consistence of which would be insufficient, previous to a long and expensive drainage, for sustaining the weight of horses. The moving power is steam, generated from the peat and water of the bog itself. The diggings from the drains furnish abundance of fuel; and the drains yield an unfailing supply of water. The prime agent, steam, is thus obtained at the cheapest possible rate; the local fuel requiring no transport, and the water no outlay in reservoirs or other constructions, to ensure a constant provision. By far the greater part of the power of the engines fixed on the machine is available, and employed to actuate the ploughs or other agricultural implements. These are moved at right angles to the line of progress of the machine, not dragged after it; the machine itself remaining stationary whilst the ploughs are at work between it, and two small auxiliary carriages, in the manner to be presently described. In commencing the reclamation of a bog, a roadway is to be first traced out in a suitable direction for the proposed operations. This is done simply by forming two drains parallel with each other, and about seven yards apart. The principal machine is launched on this roadway. No metal or material of any sort is necessary for its solidity; the machine rests on the raw bog, and bears on so large a surface of it that its buoyancy is insured. It also consolidates and dries the roadway by its pressure. The two auxiliary carriages are stationed (where space permits) at a distance of about 480 yards asunder; one on each side of the principal machine, and parallel with it. Each carriage is furnished with a large wheel, or pulley, round which a band passes, proceeding from, and returning to, the principal machine, whence it derives its motion by proper apparatus. These bands are connected with the ploughs, or other agricultural implements, which are drawn to and fro between the machine and the auxiliaries. One quarter of a mile of land in breadth, exclusive of the roadway and headlands, is thus operated upon on the two sides of the machine. The auxiliary carriages travel on four wheels, resting on planks, which form a moveable railroad. One of the planks is let into a shallow trench cut in the bog, against one side of which plank some friction rollers, fixed on the carriage, press in order to resist the pull of the engines. Ploughing is the first agricultural operation. To accomplish this process in a thoroughly mechanical manner, and to adapt it to steam power, it was necessary to contrive peculiar ploughs, furnished with sharp working knives, which divide every root and fibre of the bog plants, to the depth of 9 inches, and turn over a furrow slice of 18 inches in breadth, completely reversing the surface, and turning the heather side downwards. The underlying heath, moss, and other bog-herbage facilitates the discharge of water, and permits the rain and air to penetrate the furrows. Drains are formed as the ploughing proceeds, that the vast quantities of water liberated by that process may be immediately carried off. After lying a few months in this state, exposed to the action of the atmosphere, the ploughed surface is found to be so considerably pulverized, that little remains to be done to fit it for the reception of grass-seeds. The complex operations necessary to prepare the soil for the culture of other and more important crops than grasses, will also be materially simplified and

economised by awaiting the natural decomposition of the soil, which is so greatly expedited by this system of ploughing as a first process. It establishes a general under-drainage, which, with the assistance of numerous shallow gutters discharging into proper drains, will speedily create a soil on the surface of the wettest bogs. The machine and auxiliaries remain stationary during the time occupied by the ploughs in taking two furrows; they are then, severally, put in motion, and made to advance in three parallel lines, in order to keep pace with the breadth of land turned over, and to pull the ploughs accurately straight. The machine is impelled by the engines, and each auxiliary by its attendant man, who also shifts on his planks as occasion requires. The machine and its auxiliaries have thus to be moved over a space of 18 inches only, whilst the ploughs have travelled 440 yards, and turned over 220 square yards of land 9 inches in depth; in other words, the machine and auxiliaries have to be moved only 11 yards, in the time that the ploughs have travelled 5½ miles, and turned over a statute acre of land. The ploughs perform their work at the rate of two miles an hour, and are subject to very few stoppages; so that 8¾ acres, nearly, of bog would be ploughed up in a day's work of 12 hours, or, taking the average of daylight throughout the year, and making a liberal allowance for hinderances from weather and other causes, one machine would plough up 2,000 acres in a twelvemonth."

"Mr. Upton's steam-plough," said the prospectus of that gentleman's invention, "is worked by his patent lever steam-engine, and his air furnace boiler. If a single-shared plough, the space occupied by the entire machine will be 4 feet long by 10 feet; if for trench ploughing, the dimensions will be the same; if for ploughing two, three, or more parallel furrows at once, then the breadth and length will be about 5 feet by 12 feet. The work done by the trenching plough will be equal to any spade husbandry; and that by the parallel shares will be found very superior to any horse ploughing; inasmuch as the ground will not be trod and rammed down by horses' feet; and as the steerer or ploughman, &c., will ride on the machine, the land will be left as open and light as possible, and resemble that of garden culture. To the steam-plough a harrow, drill, and seed-box can be attached when requisite, and the entire operation performed at one going, when it is for the last ploughing, without trampling the soil. The spots left in the angles of the field by Upton's steam-plough will be smaller than by any horse-plough, as the steam-plough will turn, if a single share, in thrice the breadth and length of a common wheelbarrow; and if a three-shared plough, it will turn in the space of a small one-horse cart. The simplicity of construction and small number of parts composing this steam-engine and boiler, and the great safety and security of the latter, will prevent the necessity of frequent or expensive repairs, as the only parts of the apparatus most liable to wear and tear are the ploughshares, the soles, coulters, and harrow tines, which will only require the same repairs as if drawn by horses. The engine and its boiler is calculated to go 50,000 miles, or more, before any repairs could be wanted, unless from accident or unfair usage; and whenever, from long use, very much worn, if the boiler were to burst, it could only extinguish its own fire without injury to any person close to it. The plough will require one steady man to direct or steer it, and a tractable boy to attend the fire and turn the steam off and on occasionally, the engine being of the most simple and efficient construction. The water-tank will require replenishing now and then, and perhaps fuel will be required two or three times in the course of the day, and the boiler is admirably constructed for burning either wood, peat, or coke, or coal may be used. The single plough is calculated to do two acres per day, and as the person will not be fatigued by walking over the rough ground, nor have any horses to rub down and feed after coming home from the field, they could remain out a longer time. The double plough would do four acres, and the three-shared plough would do about six acres per day. The counter or trench plough would do about two acres per day; but as it would be equal in power to the double-shared plough, it would require the same quantity of fuel and expense. The land cultivated by this plough would doubtless be found from its efficiency to produce crops nearly if not quite equal to spade husbandry; and it would in such cases pay for the steamer the first season." The locomotive-engine was contrived also to be detached at pleasure from the ploughs, and employed in drawing manure carts to the field and carts laden with produce to the market. "And I think," said the inventor, "it might be so modified by further improvements as to be made subservient to many of the farmer's wants. It might perhaps be made available for the cutting of roots and fodder for stall-fed and other cattle; for thrashing, winnowing, grinding corn, and pumping water, &c. In case of the last ploughing, when it is intended to sow and harrow in the seed at one going, the same power would effect the whole work, only requiring the aid of the boy, who must otherwise be engaged in driving the harrow horses, but which horse labour and horse injury done to the soil would be done away with, and a further saving per acre effected by the steamer. The additional boy at the steam-harrow would be required to lift up the harrow occasionally, and take up the weeds, and put them in a basket hung to the machine, until arrived at the headland, where a spare cart might be placed to receive them, and which the engine would take out of the field every evening, or as many times per day as was necessary."

STEARINE. The constituent of oils and fats which is solid at common temperatures. See the article Oil.

STEEL. The hard carburet of iron; that is to say, a compound of iron and carbon. Its discovery was antecedent to the origin of authentic history. Pliny says that, in his time, the best steel came from China, and the next best from Parthia. A manufacture of it existed in Sweden as early as 1340; but it is the general opinion that the process for converting iron into steel, called *cementation*, originated in England. The furnace in which iron is converted into steel, has the form of a large oven, or arch, terminating in a vent at the top. The floor of this oven is flat and level. Immediately under it there is a large arched fire-place, with grates, which runs quite across from one side to the other, so as to have two doors for putting in the fuel from the outside of the building. A number of vents, or flues, pass from the fire-place to different parts of the floor of the oven, and throw up their flame into it, so as to heat all parts of it equally. In the oven itself, there are two large and long cases or boxes, built of good fire stone; and in these boxes the bars of iron are regularly stratified with charcoal powder, ten or twelve tons of iron being put in at once, and the box is covered on the top with a bed of sand. The heat is kept up, so that the boxes and all their contents are red hot for eight or ten days. A bar is then drawn out and examined; and if it be found then sufficiently converted into steel, the fire is withdrawn and the oven allowed to cool. This process is called *cementation*. The bars of steel formed in this way are raised, in many parts, into small blisters, obviously by a gas evolved in the interior of the bar, which had pushed up, by its elasticity, a film of the metal. On this account, the steel made by this process is usually called *blistered steel*. The bars of blistered steel are heated to redness, and drawn out into smaller bars by means of a hammer, driven by water or steam, and striking with great rapidity. This hammer is called a *tilting hammer*, on which account, the small bars formed by it are called *tilted steel*. When the bars are broken in pieces and welded repeatedly, and then drawn out into bars, they acquire the name of *German* or *shear steel*. Steel of cementation, however carefully made, is never quite equable in its texture; but it is rendered quite so by fusing it in a crucible, and then casting it into bars. Thus treated, it is called *cast-steel*, and sells at a much higher price than common steel. The process was contrived at Sheffield in 1750, and for a long time kept secret. When steel is to be cast, it is made by cementation in the usual way, only the process is carried somewhat farther, so as to give the steel a whiter colour. It is then broken into small pieces, and put into a crucible of excellent fire-clay, after which the mouth of the crucible is filled up with vitrefiable sand, to prevent the steel from being oxidized by the action of the air. The crucible is exposed for five or six hours to the most intense heat that can be raised, by which the steel is brought into a state of perfect fusion. It is then cast into parallelopipeds about a foot and a half in length. To fuse one ton of steel, about twenty tons of coals are expended; which accounts for the high price of cast-steel, when compared with that of iron, or even of common steel. Every time that cast-steel is melted, it loses some of its characteristic properties; and two or three fusions render it quite useless for the purposes for which it is intended. It has recently been proved that the steel of which the Damascus blades were made, and which was steel from Golconda, owed the peculiarity which these blades have of showing a curious waving texture on the surface, when treated with a dilute acid, to their consisting of two different compounds of iron and carbon, which have separated during the cooling. It is cast-steel in which the process is carried farther than usual, and which is cooled slowly; both common steel and cast-steel are formed, which separate during the slow cooling. The steel is rendered black by the acid, while the cast-iron remains white. This kind of steel can only be hammered at a heat above that of cherry-red. The specific gravity of good blistered steel is 7·823. When this steel is heated to redness, and suddenly plunged into cold water, its specific gravity is reduced to 7·747. The specific gravity of a piece of cast-steel, while soft, is 7·82; but when hardened by heating it red-hot, and plunging it into cold water, it is reduced to 7·7532. Hence it appears, that when steel is hardened, its bulk increases. The colour of steel is whiter than that of iron. Its texture is granular, and not hackly, like that of iron. The fracture is whitish-grey, and much smoother than the fracture of iron. It is much harder and more rigid than iron; nor can it be so much softened by heat without losing its tenacity and flying in pieces under the hammer. It requires more attention to forge it well, than to forge iron; yet it is by its toughness and capability of being drawn out into bars, that good steel is distinguished from bad. Steel is more readily broken by bending it than iron. If it be heated to redness, and then plunged into cold water, it becomes exceedingly hard, so as to be able to cut or make an impression upon most other bodies. But, when iron is treated in the same way, its hardness is not in the least increased. When a drop of nitric acid is let fall upon a smooth surface of steel, and allowed to remain on it for a few minutes, and then washed off with water, it leaves a black spot; whereas the spot left by nitric acid on iron, is whitish-green. Steel is not so easily converted into a magnet as iron; but, when once converted, it retains its magnetic properties much longer.

Numerous investigations have, at different periods, been made concerning the composition of

steel. In an elaborate dissertation by Monge, Berthollet, and Vandermonde, it is asserted that good hammered iron consists of *iron* free from all heterogeneous matter; that steel is a combination of iron and carbon; and that cast-iron is a combination of iron with carbon, in which the proportion of carbon is greater, and the iron not wholly free from oxygen. Dr. Thomson gives the following as the composition of cast-steel:—

Iron, ...	99
Carbon, with some silicon, . .	1
	100
